Another possibility is that the attraction may turn into repulsion at very close approach, in analogy with the forces between the atoms of a liquefied inert gas. In this case the repulsion might ensure that any one particle can, within the range of its forces, be surrounded only by a small number of others, and hence the binding energy per particle is again limited. This possibility has not been fully explored, but it has the disadvantage that, owing to the wave mechanical penetrability of potential barriers, an extremely strong repulsion would have to be assumed to make this explanation possible.

The most attractive explanation is no doubt that the forces are 'exchange forces' which depend on the symmetry of the wave function describing the motion of the particles, like the valency forces between the constituents of organic molecules. On this idea the neutron is trivalent, capable of forming a 'bond' with one other neutron and two protons, and correspondingly for the proton. This would give a very natural explanation of the helium nucleus as a saturated structure[1].

The directional properties of the forces, which must be inferred from the existence of the quadripole moment of the deuteron, may have a bearing on this question, since in a large nucleus different particles must necessarily be arranged in different directions relative to a given particle, and the forces may quite well be attractive for some pairs of particles and repulsive for others, if the directional dependence of the forces is strong[6]. This effect will give rise to some kind of saturation; whether this saturation is of the right kind, and in particular whether it leads naturally to the α-particle as a stable structure, remains to be seen.

Of the attempts to derive the nuclear forces from a more elementary phenomenon, the most interesting is the meson theory, which is based on an idea of Yukawa[11]. Yukawa supposes that the nuclear forces are due to a 'nuclear field' in the same manner in which the electromagnetic forces are caused by the electromagnetic field. This field must, however, satisfy different field equations in order to produce short-range forces, and if this requirement is coupled with that of the principle of relativity, there is only one possible type of wave equation, and the law of interaction is limited to laws of a particular type, of which the simplest has the potential:

$$V = g.e^{-kr}/r, \qquad (1)$$

where k and g are constants, and r is the distance between the particles. (Coulomb's law is a special case of this with $k = 0$). In quantum theory, just as the electromagnetic field is associated with light quanta, the 'nuclear field' will be associated with a new type of particle; the fact that the wave equation differs from that of light indicates that the rest mass of these particles is not zero, like that of light quanta, but has the finite value $hk/2\pi c$, where k is the same constant as in (1). In order to obtain a range of the right order of magnitude this mass has to be assumed to be a few hundred times that of the electron. The subsequent discovery of 'mesons' of just such a mass in cosmic rays has very much increased our confidence in the 'meson theory' of nuclear forces.

If we try to fit a law of the form of (1) to the observations on proton-proton scattering, we obtain very good agreement, but we have to choose a value of k which corresponds to a meson mass of about 300 electron masses. This is almost certainly higher than the mass of the mesons found in cosmic rays. The origin of this discrepancy is not clear.

On the meson theory of nuclear forces, mesons are capable of being absorbed and emitted in nuclear reactions provided sufficient energy is available for their creation, and they may be exchanged (that is, temporarily created by one particle and absorbed by another) even if the available energy is insufficient to liberate them. If this view is taken, conservation of angular momentum in the process requires the mesons, like light quanta, to have integral spins. (The electron, which has a half-integral spin, can only be absorbed or produced in pairs.) Zero spin would make the nuclear forces repulsive when they should be attractive, and the most likely assumption seems that of a spin of one unit, as for the photon[12].

This assumption fixes the equations of the meson field completely, but not its interaction with the proton and neutron. This interaction is governed by two terms which, by analogy with the electric charge and magnetic moment, one may term the 'meson charge' and the 'meson moment' of the heavy particles. The law (1), in particular, is obtained if the heavy particles have only a meson charge g, but no meson moment. This law does not agree with experiment in detail, since it gives neither a spin dependence of the force (as required to explain the properties of the neutron-proton scattering) nor a directional dependence that would account for the quadripole moment of the deuteron. The introduction of a 'meson moment' would help to give the right dependence[12], but the force would then increase so rapidly at short distances that the proton and the neutron would fall into another, producing an infinite binding energy. Probably this result should not be taken too seriously, since the methods of quantum theory are likely to fail for too close approach, but it would mean in any event that the quantitative study of nuclear forces would have to be abandoned until an exact description of this failure of quantum theory is available.

It has also been suggested that two kinds of mesons might exist, of which one has the spin one, the other zero spin, and with such properties that the singular terms in the interaction energy just cancel. In the crude approximation to which such calculations are usually carried out, the directional dependence of the forces would then also just cancel, together with the infinities, but it is possible that finer effects would give a sufficiently large directional variation.[13]

Lastly, there arises the question as to the electric charge of the meson. The mesons observed in cosmic rays are charged, and if one of them is emitted by one nuclear particle and absorbed by another, this will involve an exchange of charge, thus ensuring that the forces are of the exchange type, as required by the most widely accepted explanation of the saturation of nuclear forces. Such an exchange will, however, be possible only if one of the heavy particles is a proton and the other a neutron, but not for two like particles. In order to account for the equally strong forces between like particles, one has to assume the existence of neutral mesons in addition to the charged ones[14]. There is certain independent evidence for the existence of neutral mesons in cosmic rays[15]. If we take the view that the saturation of the nuclear forces is due to their directional dependence and not to their exchange character, it is, in fact, possible to attribute *all* nuclear forces to neutral mesons[6]. This would have the advantage of removing the discrepancy between the mass of the charged mesons from cosmic rays, and the range of the forces as determined from proton–proton scattering. It would mean, on the other hand, that the particles, the discovery of which was hailed as a confirmation of Yukawa's theory, had actually no connexion with the particles postulated by Yukawa.

This summary of the present state of the theory[16] closes with a number of questions to which the answer is not known. But the fact that it is possible to ask these questions at all is a sign of the rapid progress that has been made in this field in the last few years.

BREEDING DISEASE-RESISTANT PLANTS

BY DR. F. W. SANSOME,

UNIVERSITY OF MANCHESTER

THE possibility of raising varieties resistant to virus, bacteria, fungi, and insects is an attractive prospect for the practical plant breeder. Potatoes immune to wart disease, beans resistant to anthracnose, wheat resistant to rust, vines resistant to *Phylloxera*, and wheat, barley, and oats resistant to Hessian fly, eelworm, and frit fly are sufficiently well known to encourage the investigator to work on other crops. Several publications (Roemer, Isenbeck and Fuchs, Lesley and Wallace, Reddick, Painter, Jones, Johnston and Parker) have recently directed attention to different aspects of this question. The following short account is based on these publications. The accompanying table lists a few commercial crops which contain disease-resistant varieties.

TABLE I

Potatoes: *Synchytrium endobioticum*, *Phytophthora infestans*, *Alternanthera solani*, *Bacterium phytophthorum*, *Actinomyces scabies*, *Leptinotarsa decemlineata*. Virus A, B, C, X, Y.
Tomatoes: *Cladosporium fulvum*, *Fusarium lycopersici*, curly-top virus.
Cabbage: Yellow virus, *Fusarium*.
Turnip: *Plasmodiophora brassicae*.
Cotton: *Bacterium malvacearum*, *Fusarium vasinfectum*, leaf-blister mite, black scale, jaccid insects.
Beans: *Colletotrichum Lindemuthianum*, *Phytomonas medicaginis*, *Erysiphe polygone*, *Fusarium solani*, *Uromyces appendiculatus*. *Heterodera*.
Celery: *Fusarium Orthoceras*, yellow (virus).
Antirrhinum: *Puccinia Antirrhini*.
Apple: *Venturia inæqualis*, *Eriosoma lanigerum*.
Vines: *Plasmapara viticola*, *Uncinula necator*, *Phylloxera vitifolii*.
Wheat: *Puccinia graminis*, *P. glumarum*, *P. triticera*, *P. coronifera*, *Tilletia*, *Ustilago*, *Phytophaga destructor*, *Erysiphe graminis*.
Barley: *Heterodera Schachtii*, *Puccinia graminis*, *P. glumarum*, *P. dispersa*, etc., *Erysiphe graminis*, *Ustilago nuda*.
Oats: *Oscinis Frit*, *Puccinia* spp., *Ustilago avenæ*, *U. levis*.
Pisum: *Grapholita* sp., *Bruchus pisi*, *Ascochyta*.

There are several points of interest in the relationships of the hosts and diseases enumerated in this incomplete table. There is a large number of cases where the genetics of resistance is complex. Several times (wheat, tomatoes, beans, etc.) the character was shown by the early workers to behave in a monofactorial Mendelian manner. Later, the mode of inheritance was found to depend on interacting, cumulative, or duplicate factors. Thus resistance against *Synchytrium*, *Phytophthora*, *Puccinia graminis*, *Plasmapara*, *Erysiphe*, *Cladosporium fulvum*, and woolly aphis is inherited in a complicated manner. Polyploidy of potatoes, wheat, oats, and apples will account for some of the complications, and to some extent the geneticist can cope with such problems. They could be dealt with by normal breeding procedure if resistance were an easily diagnosed trait, and behaved as a stable characteristic. Resistance, however, varies continuously in some cases, from high resistance to susceptibility, and frequently resistance has to be measured quantitatively. For example, the percentage of plants which are attacked, the percentage which prevent the normal development of the larvæ, and the percentage which survive attack, all determine the resistance of a strain of wheat to Hessian fly. A more serious difficulty, however, is the fact that the attacking agent is also a living thing and consequently productive of variations. Biffen showed that black rust resistance in wheat behaved in a simple Mendelian manner. Pole Evans and others questioned the stability of the resistant forms. The apparent breakdown of the resistance is accounted for when it is realized that black rust consists of a considerable number of different strains—physiological races. These races are in large part due to mutation and segregation during sexual reproduction. They differ from one another in their virulence and in their comparative effect upon the different varieties of the host species. The establishment and the specialization of these races is a most interesting problem. For example, the resistance of varieties of beans to three physiological races, α, β, γ, of *Colletotrichum Lindemuthianum* is:

Bean variety	*α*	*β*	*γ*
Wachs Protecta	0	++	++
Doppelte Hollande Princess	++	0	0
Krummschnabel	±	++	0

(After Schreiber.)

When the number of physiological races is increased (see Table 2), the specialization of the fungal races may upset much of the plant breeder's work. On several occasions (for example, wheat, potatoes) a variety resistant to a fungus has been produced, but soon this variety comes into contact with another physiological race of the fungus against which it is not resistant.

Table 2.

Minimum number of physiological races found in some fungi.

Puccinia graminis	160
Puccinia glumarum	31
Puccinia triticina	91
Helminthosporium graminium	4
Erysiphe graminis	15
Venturia inæqualis	111+
Colletotrichum Lindemuthianum ..	50
Phytophaga infestans	4
Tilletia spp. (on cereals)	20+
Ustilago spp. (on cereals)	20+

The diagnosis of immunity, resistance, or susceptibility would be facilitated if some anatomical or physiological characteristic of the host plant could be found to be the cause of, or to be strongly associated with, immunity. The cutinization of the epidermis of *Pisum* and distribution of sclerenchyma in cereals are associated with resistance to *Aschochyta pisi* and *Puccinia graminis* respectively, while the degree of attack of *Gibberella Saubinetti* upon wheat and maize is proportional to the state of the sugar in the transition of hexose-pentose (J. G. Dickson). The more pentose the more resistant is the crop. Resistance and immunity are, unfortunately, often bound up with the biochemical and physiological reactions of the living plant. Further research work is required before the identification of these reactions can be attempted.

Commercial breeding usually does not wait for the results of the analysis of the relationship between host and fungus, but it is rarely possible to obtain success in breeding for resistance without the help of the scientific worker. The evolution of methods of testing resistance as in wart disease, of methods of crossing based on cytology as against *Phytophthora infestans*, the introduction of new species and the study of the environmental conditions under which resistance is increased are essential to the success of the practical breeder. One or two accounts of recent breeding work will indicate the wide field and problems that are normally encountered.

Blight due to *Phytophthora infestans* causes considerable damage to the potato crop. Reduced cropping, costs of spraying and other palliative measures would be greatly alleviated by the existence of varieties of potato resistant to the disease and equal to the present susceptible variety in quality and yield. Obviously, one of the first problems in the attempt to breed disease-resistant varieties is to discover whether any potato or relative of the potato shows resistance to the disease. The analysis of collections from South America made by Baur and Schick, Reddick, Hammarlund and the Russians have shown that *P. infestans* is not epiphytotic in South America, and therefore, in the absence of a basis for natural selection, we do not expect to find, except by accident, a resistant variety. All evidence indicates that the great *Phytophthora* epidemic of 1845 was of European origin and was the first occasion on which *P. infestans* and the potato met. Various non-tuberous species of *Solanum* and neighbouring genera contain immune varieties, so it does not seem unreasonable to expect that species hybridization might achieve the end in view.

Many attempts in hybridization and selection have been made by Müller, Salaman, Sutton, Reddick, Kattermann, Schick, and others. Immunity and resistance are inherited and transmitted to the progeny of crosses within *S. tuberosum*, or between *S. tuberosum* and other species, notably *S. demissum*. The mode of inheritance is variable, like immunity to wart disease. Where *S. demissum* is used as parent, the F_1 and most of the F_2 generations are immune ; when resistant varieties of *S. tuberosum* are crossed, the F_1 is susceptible, but some of the F_2 are resistant (see Schmidt, Salaman, Reddick). It is probable, as pointed out by Müller, that the polyploid nature of the potato and its relatives is the cause of the peculiar dominance, and segregation results. The potato is notably difficult to breed since many varieties have almost inviable pollen, and breeding is restricted to a few of the commercial varieties. The potato is tetraploid, while *Solanum* species may be diploid, triploid, tetraploid, or hexaploid ; *S. demissum* is hexaploid and has fertile pollen and ovules. Unfortunately, the cross $6n \times 4n$ (where the pollen of the potato, such as it is, has to be used) is the only way in which much success can be obtained in making this cross. When the F_1 is obtained, it is immune to blight and self-fertile, but very dissimilar from any potato. The long stolons of *S. demissum* are even longer in the F_1 and the tubers are very small and few (Reddick). The F_2 and succeeding generations are quite useless for selection (Reddick, 1940). Back-crossing to the potato is laborious but does produce more promising results. Immunity is now restricted to about 40 per cent of the progeny, but the immune plants are not of much value as potatoes. Continued back-crossing, like selfing, greatly reduces vigour, and one is rewarded by weak, dwarf plants with no power to form tubers.

These methods would be difficult enough if blight was a stable entity, but it is a fungus which is even more plastic than the rusts. New biological races are being formed frequently ; in Europe the formation of sexual oospores gives an opportunity for segregation, but in America, where oospores are apparently not formed, new races are also produced asexually. Berg and Röder showed that tomato late blight was a different physiological race from those of the potato, and recently (Mill) it has been shown that this tomato blight is synthesized annually from potato blight. Therefore there are true biological races and peculiar strains with distinct degrees of infection potency. For example, Reddick states that one artificial infection of the varieties President and Green Mountain will show few lesions on the President and large ones on Green Mountain, which is susceptible. But if two passages through President are made, the degree of virulence of *P. infestans* is increased so that lesions on Green Mountain and President are both large and indistinguishable. Further, Reddick and Mills have shown that even after twenty passages through the susceptible Green Mountain the higher virulence is maintained. Reddick has shown that, if there are bridging varieties of intermediate susceptibility, the virulence of *P. infestans* can be stepped up to a high degree from a culture which originally would only infect the most susceptible. Thus Reddick suggests that it is probably feasible to break down the immunity even of *S. demissum* if bridging varieties for stepping up the virulence were available. The presence in Europe of definite physiological races which possibly have arisen from sexual reproduction further complicates matters. Müller, Schick, Kattermann, and others have isolated races which are specialized in respect to the varieties which they do or do not attack.

Although these complications are encountered, several workers have succeeded in raising potatoes of fair commercial value which are resistant to the present condition of *Phytophthora infestans*. It is unfortunate, however, that the prevalence of virus disease among potatoes probably leads to greater difficulties in the commercial growing of potatoes in Great Britain than attacks of blight. Some varieties are immune, some are carriers without showing infection and others are susceptible to one or more identified viruses. Craig's Defiance, produced by the Scottish Society for Research in Plant Breeding, is field-immune to viruses A, B, C, and X. The combined study of the etiology of the disease and of the reactions of potatoes to the different viruses is yielding highly important results. Resistance to virus diseases is inherited in sugar cane, cucumber, sugar beet, cabbage, celery, tomato, and other crops.

The reaction of the host plant to attack by virus is a peculiar one (see K. Smith). Lesley and Wallace have shown that some strains of the tomato may exhibit 'recovery' from an attack of curly top virus. The appearance of 'curly-top' appears about twelve days after infection in the field. Sometimes recovery by the regeneration of new shoots takes place, and if this is early enough the tomato may produce fruit. The degree of recovery is a racial characteristic, but is also influenced by environment. Clones from a recovered plant also show a resistance to further infection by curly top. For example, out of twenty-three recovered plants which were inoculated again, nineteen showed no symptoms of the virus. On the other hand, nineteen out of twenty-seven fresh plants showed curly top symptoms after inoculation. The virus is present in the recovered plants and its virulence on fresh plants was unchanged. Similar effects can be found in the tobacco ring-spot virus disease.

The saving of the sugar-cane in Java by synthesizing hybrids of several species including wild *Saccharum spontaneum* and crossing these to *S. officinarum* is now historic. The immunity to virus derived from *S. spontaneum* could not be introduced into *S. officinarum* until the effects of the chromosome constitution upon hybridization were realized. The 'ennobling' of the sugar-cane has increased its yield, sugar-cane control, and created immunity to diseases (Bannier, Janaki-Ammal).

Parker, Jones, Johnston and Painter have recently reported the results of combining resistance to Hessian fly attack with resistance to other pests and diseases in commercial wheat. There are strains of wheat which are resistant to Hessian fly, which lays its eggs in the seed, about the end of March; the larvæ bore between the stalk and leaf sheath, and the plants shrivel and die. Resistance to Hessian fly attack is heritable, but the mode of inheritance is involved. In some cases, the larvæ develop without the plant showing damage, and in others a low amount of oviposition takes place. Of 327 American varieties, 106 gave resistant strains (only 10 per cent attack, as compared with 40 per cent susceptible in Kanred). Painter and his collaborators have recently combined the high Hessian fly resistance of Marquillo wheat with the best winter wheats. Forms are now known which show resistance to stem rust, rust, mildew, joint worm, and Hessian fly, and are equal to the best commercial winter wheats. The combination of these strains into one variety promises to give highly important commercial results. Already the Marquillo hybrids of winter wheats show low survival of larvæ of Hessian fly, low percentage of plants attacked, and a high survival rate of plants attacked under high fly infestations. These Marquillo wheats are the first to combine resistance to insect and fungus attack, and to show resistance to Hessian fly in all the wheat belts of America.

It is interesting to note that physiological races are also present in other animal enemies of commercial crops. *Heterodera Schachtii*, *Phylloxera*, for example, have been found to have races specialized for certain varieties of a species or to certain species (*Heterodera*) (see W. H. Thorpe).

The occurrence of physiological races in insects, fungi, and, for all we know, in virus diseases, deserves special consideration by the geneticist. We know from the work of Stakman and others that the characteristics which differentiate between physiological races in rusts and smuts segregate in crosses between these different races. Also we know that mutation occurs both in sexual and in asexual generations. Rarely is there any morphological difference between these races; but fungi such as *Venturia inæqualis* produce many morphological variants on one apple. The nature of the resistance of the host variety is not simply a quantitative degree of virulence, but there is a qualitative difference respecting host varieties attacked. The simple example of *Colletotrichum*, quoted above, may be extended to the larger number of varieties available in the host species.

How did these physiological races spread after their origin by mutation or segregation? The origin of new physiological races in the asexual generation, as in the *Phytophthora* case of Reddick, mentioned earlier, is intriguing. It will be noted that virulence is only stepped up when bridging strains of the host variety are present. It might appear, therefore, that environment was creating the new variant. It is more probable that somatic mutation is continually going on. In a susceptible variety *A*, selection is neutral, and the size of the population of a more virulent mutant is small; therefore, as shown by Sewell Wright and Dobzhansky, the variant will tend to disappear. If, on the other hand, there is a bridging variety, selection for the virulent variant becomes positive, and the population grows in size. Therefore the more virulent strain of fungus is ready in the bridging variety in sufficient amount to infest the more resistant host variety *B*. Once established there, the less virulent race of fungus tends to be swamped. Specialization of a fungus race to a particular variety would arise if the virulent race of fungus became modified by mutation and selection in such a way that it would not attack the original susceptible variety *A*.

OBITUARIES

The Right Hon. H. A. L. Fisher, O.M., F.R.S.

DEATH has been taking a heavy toll of eminent Oxford men within the last few months. First, Prof. Joachim died about a year ago; then his intimate friend Prof. J. A. Smith; then Prof. Samuel Alexander, who had made his name at Lincoln College before he went to Manchester. Then, on April 18, came the death of Mr. H. A. L. Fisher, who was, of course, much the best-known public man of the group. In one way he must surely have been unique, in giving many years of service as a Minister of the Crown and then having a long tenure of the wardenship of New College, Oxford.

Fisher was taken into the war cabinet as Minister of Education by Mr. Lloyd George—to whom he was always much attached—in the year 1916 when the great changes were made which displaced Lord Asquith. He remained as Minister of Education until 1926 and used his position to make the most vigorous efforts to raise the standard of national education by raising the age for leaving school and in other ways improving the chances of education for young people when they came to leave. In these efforts he gained the hearty support of the whole teaching profession, whose status he considerably improved by raising the salaries of masters and mistresses in secondary schools.

No one perhaps has ever deserved so much of the whole body of teachers and scholars as did Mr. Fisher. It will be remembered that it was found impracticable to carry out at once the raising of the age which his Act proposed. The matter was left in abeyance and in constant dispute until the present Government took it up again two years ago and—with certain reservations—at last made the Fisher Act a living thing. How it will work remains to be seen when the modifying Act is at last to be put in operation.

On leaving the Ministry in 1926, Fisher went back to his old College, this time as head, for he had been by education a Winchester and New College man. He remained as warden of New College until his death, and was one of the best-known and respected figures in Oxford.

In the world of letters he became best known by his "History of Europe", which quickly rose to the distinction of a best-seller. It was published in 1936 after intense labour which reduced Fisher to a chronic state of weak health for the last three or four years of his life. He tells us in the preface that his subject is "Man from the neolithic age to Stalin and Mustapha Kemal, Mussolini and Hitler". But he damps the hopes of believers in progress by saying that "one intellectual excitement has been denied me. Men wiser and more learned than I have discerned in history a plot, a rhythm, a predetermined pattern. These harmonies are concealed from me. I can only see one emergency following upon another as wave follows upon wave. There can be no generalization, only one safe rule for the historian; that he should recognize in the development of human destinies the play of the unforeseen and the contingent". It was true indeed in the course of his own life, for who could have foreseen that the best-known historian in England and the leading figure in Oxford academic life would have been struck down at last by a lorry on Millbank. His friends had been anxious for his health for some years. They thought that he would yield to the strain of excessive and prolonged intellectual work. But no! It was the contingent, a passing lorry, which might have carried away any insignificant citizen of London, which ended one of the most active and distinguished lives of our day.

F. S. MARVIN.

Prof. S. M. Dixon, O.B.E.

PROF. STEPHEN MITCHELL DIXON, who died on March 25 at Nice at the age of seventy-four, was a leader in civil engineering education. Born in Dublin, he studied experimental physics and carried out research under Fitzgerald at Trinity College, and then qualified in civil engineering. After experience as contractor's engineer on railway works in England he was appointed to a newly established chair of civil engineering at Fredricton, New Brunswick, in 1892. Ten years later he moved to Dalhousie University, Nova Scotia, and in 1905 was called to Birmingham to organize the Department of Civil Engineering. When, in the general re-organization following the formation of the Imperial College of Science and Technology, the Mechanical and Civil Department of the City and Guilds (Engineering) College was divided into two autonomous departments in 1912, Dixon was called to the chair of civil engineering there.

Dixon was a great teacher who had the gift of infecting those around him with some of his own unlimited enthusiasm and of getting the best out of his students and staff without apparent effort. He had the probably unique record of having started four university departments of civil engineering. Dixon's approach to his subject was practical rather than theoretical, and he combined a sound foundation of the mechanical principles with a deep distrust of complicated theories and involved calculations. His fertile and active mind led him to devise many new ways of tackling well-known problems—a typical example was the use of a sand core for moulding pre-cast hollow concrete blocks. Old students will remember how he built a house, almost unaided, to prove the practicability of this pre-cast block.

In his earlier years, Dixon carried out research on terrestrial magnetism and on surveying instruments, but the ampler resources at Birmingham enabled him to begin the large-scale experiments on structural members which were perhaps his most important contribution to engineering science. This method of investigation was first applied to reinforced concrete beams, slabs and arches, and afterwards, at the Imperial College, to mine supports—steel and concrete arches for roadway lining, and cogs, chocks and packs for face support.

At Birmingham, Dixon carried out investigations on wire ropes and on supports for the coal mining industry, and this work was resumed when he was appointed to the Safety in Mines Research Board in 1923. He acted as chairman of the Wire Ropes Research Committee, and organized international co-operation in these investigations. Dixon was also a member and sometime secretary of the Institution of Civil Engineers Committee on the Deterioration of Structures in Sea Water, and carried out a long series of investigations on the preservation of Empire timbers from attack by Teredo. He served on the British Standards Committees dealing with wire ropes and steel arches for mines, and also on the testing of timber and the rating of rivers. In the large hydraulic laboratory at the Imperial College various investigations on current meters, syphons, and river models were carried out under his direction. For his work describing the measurements of the flow of the River Severn in 1921–36 he was awarded a Telford Premium of the Institution of Civil Engineers.

No record of Dixon's life would be complete without a reference to his outstanding services during 1914–18. In the very early days of the Ministry of Munitions he became personal assistant to Sir Henry Fowler, director of production, and was actively engaged in the organization of the great department until relatively stable conditions were reached in 1917, when he resigned to join the Royal Engineers. After ten days training he went to France on railway construction, and was demobilized as a captain in 1919. Dixon retired from his chair at the Imperial College in 1933.

M. A. HOGAN.

Profs. Jan Włodek and Adam Różański

PROF. JAN WŁODEK was one of the seventeen Cracow professors who recently died as a result of ill-treatment by the Germans in the concentration camp at Sachsenhausen, near Berlin. This was a disused brewery, had no accommodation for human beings and, although not quite as bad as the notorious Dachau and Buchenwald camps, was utterly unfit for human habitation. Along with 149 of his colleagues, he was arrested by the Gestapo, the accusation being, to quote the official Polish report:

"(1) vu que les professeurs ont essayé de reprendre les cours de l'Université sans que les autorités allemandes eu aient connaissance ;

"(2) vue qu'ils ont continué leurs travaux dans les institutions et séminaires dont ils étaient à la tête et faisaient passer des examens sans en demander l'autorisation ;

"(3) vue que, pendant 5 siècles, l'Université de Cracovie a été un bastion de l'esprit polonais. . . ."

He was by no means a robust man and as soon as his friends heard that he had been arrested it was feared he could not survive the cruelties to which he would be exposed, nor did he.

Prof. Włodek belonged to the old Polish nobility, had studied in Poland and in Switzerland, working especially on plant nutrition and soil problems and also on plant breeding. When the new Polish State was set up he, as one of the followers of Pilsudski, was appointed to consular work in Holland, but soon returned to the University of Cracow as professor of agriculture. Here he set up a large laboratory and was put in charge of the University Experimental Farm of Mydlniki. He was an excellent teacher and attracted many pupils, two of whom had already become professors at other Polish universities. Almost from the outset he was attracted to Willstätter's investigations on chlorophyll and was especially interested in the ratio of chlorophyll A to chlorophyll B, which he considered played an important part in the development of plants. He studied the relation between this ratio and the environmental conditions, particularly variations in the amount of nitrogen and of potassium supply. The other branch of his work was ecological and dealt with the distribution of plants in the Tatra Mountains in relation to the humus and calcium conditions of the soils and their pH values.

He had travelled widely in Europe and was a remarkably good linguist, speaking and writing English perfectly. He was a delightful host and those who have been privileged to visit him in his attractive ancestral home at Dabrowica will not easily forget his wide culture, good taste and charming personality.

Another victim has been Prof. A. Różański who, before the War of 1914–18 had held an important post in the Government in connexion with land surveying and improvement. After the War he was appointed professor of agricultural engineering and surveying in the University of Cracow and did a good deal of work on land drainage, particularly important for the development of agriculture in many parts of Poland. He showed considerable ingenuity in designing inexpensive and efficient methods of draining. He rendered great service to Poland in a quiet and unobtrusive way and was much liked by his students.

E. J. RUSSELL.

We regret to announce the following deaths:

Dr. Carl Bosch, president of the I. G. Farbenindustrie, the German dye trust, on April 27, aged sixty-six years.

Dr. Charles Davison, the authority on earthquakes, on April 28, aged eighty-one years.

Sir William Meade-King, the well-known civil engineer, on April 10, aged eighty-one years.

NEWS AND VIEWS

Dr. T. A. Henry

THE Wellcome Foundation recently made a presentation to Dr. T. A. Henry to mark the completion of his twenty-first year of service as director of the Wellcome Chemical Research Laboratories. Dr. Henry began his research career as a Redwood scholar in the Research Laboratories of the Pharmaceutical Society, whence he moved to the Scientific and Technical Department of the Imperial Institute, where he held a Salter's Company research fellowship and ultimately became superintendent of laboratories. He was appointed to his present post in 1919. Dr. Henry has done much original work on natural products, particularly cyanogenetic glucosides and alkaloidal drugs, while in his applications of chemistry to progress in medicine he has covered a very wide range of subjects.

During his directorship of the Wellcome Chemical Research Laboratories, Dr. Henry has given considerable attention to the chemotherapy of tropical diseases, including hookworm, leprosy, kala azar and malaria. This has involved investigations on the chemistry of organo-metallic compounds of arsenic, antimony and mercury, and has led, among other things, to a thorough examination of apoquinine, apoquinidine, niquidine and niquine and to the elucidation of their chemical constitution. Recently, the laboratories under his direction have been exploring the relationship of chemical structure and bactericidal action in the new group of drugs starting from sulphanilamide. In 1927, Dr. Henry was awarded the Hanbury Medal, which is given periodically by a committee including the presidents of the Chemical, Linnean and Pharmaceutical Societies for "high excellence in the prosecution or promotion of original research in chemistry and natural history of drugs". He is the author of the well-known text-book on the "Plant Alkaloids", of which a third edition was issued last year.

Scientific Research and Taxation

AT a time when the financial position of learning and scientific research is a matter of serious concern, no little interest is attached to the decision of a Divisional Court when Mr. Justice Hawke, Mr. Justice Charles and Mr. Justice Tucker on April 25 dismissed an appeal by the School of Oriental and African Studies of the University of London (*The Times*, April 26). The appeal was from the decision of the County of London Quarter Sessions that the School was not exempted under Section 1 of the Scientific Societies Act, 1843, from the payment of rates in respect of certain premises occupied by it. The provisions of this Act, by which a "society instituted for the purposes of science, literature, or the fine arts exclusively" may be exempted from the payment of rates, but of which full advantage had not been taken for some time, were successfully invoked by a number of learned and scientific societies in the financial stringency which followed on the War of 1914–18. It was a further manifestation of the favourable attitude of the authorities towards learning and research at this time, when not only was exemption from income tax allowed or continued to scientific societies which in addition to serving the interests of their members could be shown to be carrying out work of public utility, but also an additional concession made income tax recoverable on subscriptions guaranteed over a period of years.

It may seem that there has been a change in the spirit which prompted this last concession in Sir John Simon's statement last week that he is not prepared to propose an alteration of the law, which at present makes no provision for exempting benefits for research from estate duty. At the present time this decision is not surprising; but it is a matter which scientific bodies and organizations interested in research should not allow to go by default when a more favourable occasion arises. The trend of the application of financial legislation in the last hundred years has been to free the pursuit of learning from the burden of taxation so far as possible. In the days of financial stringency which the future will bring, estate duty will inevitably prove a heavy burden on posthumous endowment of research, unless a change is made.

Family Allowances

THE question of family allowances is discussed by a recent broadsheet issued by Political and Economic Planning (P E P), and in a new pamphlet by Miss E. F. Rathbone, "The Case for the Immediate Introduction of a System of Family Allowances and Alternative Proposals for such a System", issued by the Family Endowment Society, 72 Horseferry Road, London, S.W.1. The broadsheet points out that family allowances have become a live issue to-day for three main reasons: the need to restrict civilian consumption while safeguarding basic standards of health and nutrition; the claim for 'equal pay for equal work' which may arise sharply in the munitions industry if large-scale replacement of male by female labour occurs; and the need, intensified by new types of war-time distress and the multiplication of assistance scales, for codification of the numerous regulations. To relate income to the extent of family responsibilities is the only way of preventing the general reduction of consumption, however effected, pressing unfairly on large numbers of children. Wages are not only a payment for work done but also the means for rearing and maintaining a family, and all agencies by which consuming power is diverted from the social pool for the benefit of dependent wives or children are, in fact, agencies for family endowment. Miss Rathbone contends that family allowances offer the best means of meeting unavoidable increases in living costs simultaneously for workers in all occupations with similar family needs, without stimulating a race between prices and wages.

Both Miss Rathbone's review and the broadsheet discuss systems and experience in other countries, and favour a national service, State-regulated and State-administered. Tabular statements included in Miss Rathbone's pamphlet show that the charge on the Exchequer ranges from £118 million for a State-paid scheme, covering all children under fifteen years of age in Britain at 5*s*. per child, to £6½ million for the State share of a contributory insurance scheme, covering only the population insured for unemployment at 3*s*., beginning with the second child. Miss Rathbone prefers a bold imaginative scheme, covering the entire child population at the rate of 5*s*. a child, on the grounds of justice, for eugenic reasons and because of the greater simplicity of administration. If this is considered too costly, a contributory insurance scheme is urged involving an Exchequer contribution of £6½–£32½ million. Whatever the scheme, payment of the allowance to the mother is strongly recommended, partly to diminish the attraction of the labour market to married women and partly to emphasize that the allowance is not part of the remuneration of labour, but a recognition of the child's value to the community.

An International Air Force

A PLAN for the organization of an International Air Force is outlined in the report of the Military Research Committee of the New Commonwealth Institute, which was printed just before the outbreak of the War but has only now been issued. The scope of the proposed Force is as a reinforcement of the self-defence of States, adequate to give each the sense of security from attack that its unaided strength, alliances, or guarantees of neutrality are unable to ensure. The scheme could only operate if a sufficient number of States consented to cooperate, and the report points out that absolute neutrality is inconsistent with co-operation against war by any plan. Associated States would make an annual contribution to a common pool, in equal proportion to their total resources or war budgets. The assistance afforded to each assured State would be the maximum possible and not determined by the amount of its contribution. After discussing the advantages and disadvantages of the alternative systems of a Force composed of national quotas and an independent organic Force recruited by voluntary enlistment, the report strongly recommends the latter. It is essential, that the Force should be as efficient, as homogeneous, and as certain to act when required as is humanly possible.

In regard to language, the Committee recommends the adoption of Spanish, and it is suggested that each contributing State should provide a base with extra-territorial status in its territory for the Force, this distribution of bases giving a wide area of protection, while the Force should have the maximum possible freedom of movement both in peace and in war. In regard to the supply of aircraft, the Committee contemplates drawing on the manufacturing resources of private firms in all States sufficiently prominent in aviation, and manufacture would be directed and supervised by a design department, a research department and an inspection department serving the Force. The contributing States would be represented on the Board of Control, although the Force would have complete internal autonomy and the power of executive initiative. In addition to an intelligence service, the High Command would be provided with simple standing orders to ensure rapid action after determination of the facts. The scheme is regarded as well within the ability of European and adjacent States to finance, organize, equip and recruit.

Regional Organization and Local Government

IN a paper entitled "Regional Organization during and after the War" read before the Royal Society of Arts on February 7, Brigadier Sir Edward Tandy described the regional organization developed for defence purposes and discussed its adjustment to meet peace-time requirements after the War. Reviewing our existing peace-time machinery for local government, which he urged must be accepted but reinforced by regional organization to meet emergencies like that of war, Sir Edward Tandy suggested that the easiest way to establish the regional organization required for peace would be to accept the system established for war and retain a suitable nucleus of staff at each regional headquarters. These headquarters would be available almost at once to form advisory committees to consider how new measures of reconstruction could be best applied to each region, or the best distribution within each region of any funds which might be allotted by the central Government for particular purposes. They could also assist as liaison officers in smoothing difficulties between the central Government and local government authorities and the like, and Sir Edward suggested that the commissioners should be designated Commissioners of Public Welfare, to indicate the wide general scope of their activities. Such regional organization could easily be discarded if it proved to be superfluous, but Sir Edward indicated the difficulties which are at present continually arising in the absence of a regional system for peace-time purposes.

The Zoo during War-time

THE report of the Zoological Society of London presented at the annual meeting on April 29 shows that after the first great drop in public visitors last September to 11·3 per cent of the figures for the corresponding period of the previous year, there has been a healthy recovery. The Society is to continue its publications at about half the normal scale; 180 animals have been 'adopted' under the Society's war-time scheme to cover feeding costs and there have been developed photographic competitions to encourage amateur photography at the Zoo, and exhibitions of war-time utilities in food production in the way of goat, poultry, rabbit, pig, pigeon and bee keeping. A committee has been formed to revise the more obsolete of the by-laws, and the alterations will be put before the ordinary general meeting this month and balloted upon in August. Notable changes in staff have been the retirement of the curator of mammals and birds, and of the librarian, with temporary termination of the duties of the director of the aquarium (who is now working at the War Office), and of Mr. Bushby and Mr. Fisher.

British Museum (Natural History): Recent Acquisitions

THE Zoological Department has received from Mr. I. R. P. Heslop two skulls of the pigmy hippopotamus (*Chœropsis liberiensis*) which came from the Owerri and Warri Provinces in southern Nigeria. The interest in these two specimens lies in the fact that the distribution of this species was formerly held to be confined to a comparatively small part of West Africa, namely, to Sierra Leone, Liberia, and the French Ivory Coast. The Museum has received rumours from time to time during the past few years of the existence of the pigmy hippopotamus over a much greater range than was formerly thought to be the case. The occurrence of this species in southern Nigeria shows that its distributional area is very much greater than was assumed.

Major J. F. E. Bowring, of Ickingham Hall, Bury St. Edmunds, has presented to the Department of Mineralogy an exceptionally fine specimen of Burmese amber, probably the largest preserved in any museum. The specimen has a rich, dark brown colour, and is brightly fluorescent in ultra-violet light. It measures 22 in. × 14 in. × 7 in. and weighs 33 lb. 10 oz. The largest specimen of amber so far recorded is one weighing $21\frac{1}{2}$ lb., of lighter coloured Prussian amber, preserved in the Mineralogical Museum of the University of Berlin. The Department of Mineralogy has also acquired some crystals of pale green actinolite from Mogok, Burma. These are the first specimens of the amphibole family from that locality to be represented in the collections. The crystals are of gem quality, and, although they possess the good characteristic prismatic cleavage, the mineral more usually occurs in fibrous aggregates like tremolite asbestos.

Large-Scale Plankton Cultures

H. Pettersson, F. Gross and F. Koczy have published an account of large-scale plankton cultures using the plankton shaft of Pettersson's new institute (*Medd. Oceanogr. Inst., Göteborg*, No. 3; 1939). The shaft is cylindrical, 12 metres deep and 2 m. in diameter. Interaction between the concrete walls and the sea-water has been avoided by coating the latter with a British rubber composition 'Semtex', on which a cellulose white paint had been sprayed to lighten the dull grey. The tank was filled with a mixture of sea-water from the Bay of Biscay and fresh water, and was manured with nitrate, phosphate, silicate and filtered soil extract. The water was run in from the bottom after sterilization by passage over a mercury arc lamp. Layers of different salinity and temperature were formed, the temperature being kept down in the upper less saline layer by means of cooling coils. Illumination was supplied by sodium and mercury lamps and was usually maintained at 30–40 kilolux at the surface.

With a large crop of phyto-plankton or flagellates in the water the light intensity was reduced to 50 per cent in a depth of rather less than a metre, and at the lower limit of the culture medium layer, 550 cm. thick, the light had fallen to the level of the compensation intensity, about 500 lux. Samples of phytoplankton and zooplankton from the Swedish coast were introduced into the upper layer, which was usually at 7°–9° C. Good growth was obtained and observations were made upon the vertical distribution of the animals as a phototropic response. Quantitative measurements were made at intervals of the changes in the diatoms, autotrophic flagellates and copepods. Thus the first steps have been taken in the development of a valuable method for the study of plankton in an immobilized water column in which the physical and chemical conditions can be varied at will. An observational is thus transformed into an experimental science.

Phenology of 1939

THE Royal Meteorological Society's Phenological Report for 1939 has been issued with its usual abundance of statistics and diagrams (Roy. Meteor. Soc., London. 3*s*.) It is interesting to note that the work is to continue, despite the War, and that other organizations like the British Empire Naturalists' Association and the Rothamsted Experimental Station are co-operating. There is a total of 385 observing stations compared with 439 in the previous report, and a scheme has been prepared to meet the growing demand for a simple method of assessing and demonstrating, at intervals throughout the year, the state of the season in the British Isles, making use of the Society's organization. In order to replace some unsatisfactory plants on the list, flowering dates are being made for the first time of *Cardamine pratensis*, *Acer pseudoplatanus*, *Viburnum opulus*, *Digitalis purpurea* and *Calluna vulgaris*. The historic phenological observations at the Marsham district of Norfolk, which have been made since 1736, are being continued.

With regard to meteorological effects in Great Britain during 1939, the severe December-January cold did not affect plant-life generally; the subsequent warm spells produced forwardness with a tendency to persist, especially with regard to insects, the larvæ of which experienced early favourable conditions for feeding up after hibernation. The general influence of the year, so free from extremes, was favourable to fruit, cereal and root crops (in striking contrast to the previous year), and wild fruits were also plentiful; absence of severe gales and early frosts resulted in brilliant autumn tints and the second flowering of many plants. Spring bird migrants generally tended to lateness in arrival. Of migrant insects, *Vanessa cardui* appeared in considerable numbers, but the weather was unsuitable for the larvæ to produce many autumn specimens. *V. atalanta* and *Colia croceus* were scarce, but striking immigrations of *Pieris rapæ* and *P. brassicæ* from all parts caused great damage to greens. Generic names in full have now been added to the index table and nomenclature is brought up to date. The promptness of the appearance of the report under the difficulties of present conditions is most encouraging to all the voluntary workers concerned.

Australian Aboriginal Artist

ILLUSTRATIONS accompanying the printed report now available of a communication presented at the Canberra meeting of the Australian and New Zealand Association for the Advancement of Science which dealt with aboriginal sculpture render possible an independent judgment on material the discovery of which is hailed by the author, E. P. Goddard, as "one of the most noteworthy finds in many years" (*Report. 24th Meeting Aust. and N. Zealand Assoc. Adv. Sci.* 1939, Sect. F., Anthropology). The sculpture is the work of a woman of about thirty-two years of age, Kalboori Youngi by name, and a member of the Pitta-Pitta tribe. She is obviously a sculptor of natural genius, producing carved human figures remarkable both for their modelling and their detail, as well as their feeling for the disposal of mass and line. She works in two kinds of clays, of which one is used in the composition of the 'widow's caps' used in mourning rites. Her tool at first was a fine flake of quartzite, but she now employs a pocket-knife which has been given to her.

Although the Pitta-Pitta are now in contact with station-life, Youngi has not come under mission influence, nor has she seen sculpture of any kind. The Pitta-Pitta tribe is described as "virtually a tribe of hereditary artists", apparently on the ground that that part of the Diamantina of central western Queensland, more especially Brighton Downs station, contains numerous rock-drawings, paintings and carvings in caves and on rocks "executed long before the white man took up his pastoral holdings". The familiarity with graphic art may suggest the orientation of the aboriginal sculptor in seeking a form of self-expression, unusual and unexpected though it may be, but the derivation of the medium of expression, the sculptor's art, still seems obscure. The sculptures consist of human figures, male and female, singly and in groups, with horses and dogs as accessories rather than main elements in the composition in a manner which suggests the technique of European portraiture. The author compares this work with early Mesopotamian and Egyptian, but the comparison which suggests itself is with Sumerian, and notably the statue of Gudea.

Electrical Development in Ireland

FOLLOWING the reading by Mr. P. G. Murphy of a paper on "The Electricity System of Eire" at a meeting of the University College (Dublin) Engineering Society, Mr. Sean McEntee, Minister for Industry and Commerce, said that he agreed with the author's estimate that in normal circumstances the demand for electricity in Eire might be expected to double itself within a decade, so that the country would then be using about 800 million of electric units yearly. By interconnecting the electricity systems of Eire and Northern Ireland this was quite feasible. It did not necessarily follow that in normal circumstances the exchange of normal power would be very large, but the interconnexion would undoubtedly help to reduce the amount of stand-by plant to meet emergencies, and would enable provision to be made for security of supply at a far lower cost than could be made by either system independently. Perhaps this development may be hastened by the present abnormal situation.

From the experience of the Electricity Supply Board, a combination of water-driven stations and fuel-burning stations is essential in Eire. The Shannon scheme has reduced the dependence of Eire upon foreign fuel to about 220,000 tons of coal yearly. On the other hand, the Electricity Supply Board's accounts still shows that during the year ended March 31, 1939, £95,000 was spent on fuel, most of which was imported. Next to the Shannon and the Liffey, the Erne and the Boyne appear to be the most important rivers from a hydro-electric point of view. The Boyne might produce an additional 100 million kwh. per annum, but its development might be very unsatisfactory owing to high rates of compensation to landowners. The Erne, if satisfactorily developed, might give an annual output of 200 million kwh., but its storage facilities and a large part of its catchment area lie within the six counties of the north—a fact which has created a very difficult problem in drainage for the Government of Northern Ireland. Mr. McEntee believes it possible to develop the hydro-electric potentialities in such a way as to improve considerably the drainage in the area affected, but any such proposals would require the active co-operation of Northern Ireland and Eire.

Roads with a Cotton Fabric Basis

IN the United States of America there is a widespread interest at present in the new 'cotton roads' which are being made across the continent from New York to California and from Florida to Maine. According to an article published in *Roads and Road Construction* of April 1, the modern procedure in construction is to lay the cotton fabric on a surface treated with bituminous material. The bituminous material is then applied to the fabric and completely covered with crushed mineral aggregate. The crushed cover material is rolled in and a lighter application of bituminous material is applied and covered with a layer of chips, which are rolled in with a heavy roller. The best results in cotton roads have been obtained from cloth of comparatively open weave. The breaking strength varies between 25 and 45 lb. (grab method) according to grade. The most practicable fabrics cost between 450 and 750 dollars a mile for a road 18 ft. wide.

In New Jersey, cotton fabric and tar were applied on 600 linear ft. of a gravel road in South Brunswick township. After a year of service an inspection was made. Due to snow and light rain for two days the road and adjoining ground was saturated. On the part of the road where the fabric had not been used, the surface was broken in twelve places. Broken areas were 0·5–1·5 sq. ft. in area and were quite soft. In other places the surface was resilient and water would ooze to the surface under pressure with a blunt instrument. On the other hand, there were no broken places in the section which had been treated with cotton fabric, and the surface was tougher and less easily punctured with a screwdriver. Recent reports sent in from a number of highway departments indicate that short test sections of bituminous-surfaced roads, having cotton as part of their construction, have decreased maintenance costs and require less patching. The South Carolina Highway Department has used cotton fabric on bridge surfaces also with a marked degree of improvement in maintaining a satisfactory bituminous surface.

Progress in Stereo Plate Casting

A PAPER on stereo plate casting published in the *Electrical Review* of March 8 gives a survey of the progress made in the application of electric heating to autoplate machines for the production of stereo plates for rotary printing presses. For several years past much has been done in the United States, and pioneer work in England took place so long ago as 1930 at the *Daily Mail* offices in Manchester, where four electrically heated autoplate machines loaded at 120 kilowatts each represented, it is claimed, the first electric printing works foundry in Europe. The next major move was not until about a year ago, when Allied Newspapers Ltd. decided to electrify completely the autoplate installation at their Manchester offices.

The electric autoplates are fitted with baths each having a capacity of about 7½ tons of stereo metal, which, when casting is in progress, is kept molten at about 650° F. and at about 450° F. during stand-by periods. It takes about two minutes to raise the temperature from 450° to 650° F. The special immersion heaters are of grid construction, and in the largest machines have an installed heating load of 264 kw. This is probably the first time that metal-sheathed tubular heaters have been directly immersed in cast metal, and the result has been most efficient operation. Since the completion of the Allied Newspapers installation, electric heating has also been introduced at the foundries in Manchester of Odhams Press, Ltd., and the *Manchester Guardian*. In the later units there is automatic temperature control.

Carnegie Trust for Scottish Universities

THE latest report of the Carnegie Trust for the Universities of Scotland shows the varied and substantial aid given. The grants are arranged in quinquennial distributions, the seventh of which covers the years 1935–1940. An aggregate of £257,300 was allocated to the universities and extra-mural institutions. The Trust is generally associated with libraries and students' fees, but it also does a good deal for specialists engaged in scientific research, and it is satisfactory to read the good reports of their work, which is as wide as in former years, and maintains an excellent standard. Several of the fellows and scholars have secured places which render them independent of the Trust. The subjects studied range from the Atlantic grey seal in the Western Islands to protein metabolism and a new synthesis of compounds of therapeutic value. The Trust subscribes to the production of good books not likely to have a popular sale and to such enterprises as a further study of the Roman occupation of southern Scotland, aided by spotting from the air.

We notice in detail that in the Glasgow, Edinburgh, and Aberdeen centres agricultural colleges have received £200 a year each. St. Andrews has had £33,150 for alterations and extensions in the five years, and Glasgow, towards the cost of the new Chemistry Institute, £59,000. The Edinburgh accounts include £13,000 for a lecturer in English, also large sums for the endowment of prehistoric archæology and ethnology, while the Men's and Women's Unions are each put down for £3,000. Equipment for medical departments of the University comes to £7,250. Arrangements have been made to meet the difficulties caused by the War.

Chemical Research in Australia

THE Commonwealth Government has approved a further addition to the activities of the Council for Scientific and Industrial Research. A division of industrial chemistry is to be established with headquarters adjoining the recently erected Aeronautical Research Laboratory at Fisherman's Bend, Port Melbourne. £50,000 has been provided for the initial building and its equipment, and abundant space is available for later extensions. After prolonged discussions with leading industrialists, it has been decided to concentrate upon study of certain aspects of each of the following major lines : (1) non-metallic minerals and their utilization ; (2) metals and alloys, particularly from the point of view of corrosion ; (3) leather, hides and fellmongery ; (4) dairy products ; with (5) a miscellaneous group where work will begin on paints and varnishes. Dr. I. W. Wark has been appointed to control the work of the division.

Minerals of Canada

A USEFUL publication which has made its annual appearance is "The Canadian Mineral Industry in 1938" (Dept. of Mines and Resources, Mines and Geology Branch, No. 804. 25 cents). It gives the output of all important mines in Canada and the destination and use of the product. It is noteworthy that Canada, in its pitchblende deposit near the Great Bear Lake, shares with the Belgian Congo the source of nearly all the world's radium. The Canadian output has caused a considerable fall in the price of radium in recent years.

The International Seismological Summary

THE International Seismological Summary for January, February and March, 1934, has just been received. Apart from individual studies of earthquakes it gives the final determinations of the epicentres and starting times of all earthquakes sufficiently recorded at seismological observatories to make such determinations reasonable. The criterion has now been made "three consistent observations of P and S" to justify the determination. During the first quarter of 1934 there were 127 earthquakes whose epicentres were found; 47 of these were new and 80 were repetitions from old epicentres, showing the tendency of earthquakes to recur in any one place where an earthquake had once happened. All except six of the earthquakes had a normal depth of focus. The six exceptions were all of deep focus. The deepest recorded earthquake during the quarter was on January 18, 1934, with a depth of focus of 0·09 of the earth's radius, or about 360 miles. Its epicentre was lat. 22° S., long. 180°, which is in the Pacific Ocean to the south of the Fiji Islands, a well-established zone for deep-focus earthquakes.

Recent Earthquakes

THREE earthquakes of considerable severity have recently been recorded at European observatories, and a fourth has been experienced. The first was on April 13 and was recorded at De Bilt (Holland) at 6h. 34m. 56s. G.M.T. The epicentre was at a distance of rather more than 20° from De Bilt. The second was registered at De Bilt on April 16 at 6h. 19m. 30s. and at Kew at 6h. 19m. 33s. G.M.T. Dr. G. van Dyk considers that the epicentre of this shock was likely to have been in the region of the Aleutian Islands. It gave rise to ground amplitudes of 0·031 mm. at Kew. The third shock, which caused ground amplitudes of 0·05mm. at Kew, was registered there on April 16 at 6h. 54m. 53s. G.M.T. It also appears to have originated near the Aleutian Islands. The fourth earthquake was felt on the night of April 26 at Gropperia in Calabria, Italy. The same shock was felt at Soverto and Vivo Valentia, but no damage was done. Calabria has been the scene of intense seismic activity on numerous occasions in the past; but notably between February 5 and March 27, 1783, when 181 towns and villages were completely destroyed and more than 30,000 people killed. These Calabrian earthquakes were, according to Lyell, "the first example of a region visited, both during and after the convulsions, by men possessing sufficient leisure, zeal, and scientific information to enable them to collect and describe with accuracy such physical facts as throw light on geological questions".

Announcements

AFTER due consideration, it has been decided not to abandon the next meeting of the Australian and New Zealand Association for the Advancement of Science, which is due to be held in Adelaide in August. The meeting will, however, be shorter than usual and few of the normal social engagements will be included. The meeting is expected to commence on August 12 and end on August 16. The incoming president will be Dr. Patrick Marshall, testing officer in the Public Works Department, New Zealand, in succession to the late Sir Ernest Scott, whose death last year was a severe blow to the Association.

THE following officers of the North East Coast Institution of Engineers and Shipbuilders have recently been elected: *President*, Mr. W. A. Woodeson; *Vice-Presidents*, Mr. J. Ramsay Gebbie, Mr. N. M. Hunter and Mr. John Neill; *Hon. Treasurer*, Mr. W. H. Pilmour.

MESSRS. FREDERICK WARNE & CO., LTD., Chandos House, Bedford Court, Bedford Street, London, W.C.2, have published a leaflet giving advice on how to assist in saving the lives of wild birds around our coasts, which have landed in patches of oil and have become helpless. The leaflet can be obtained free of charge.

AN arrangement has been made between Messrs. Newton and Co., of 72 Wigmore Street, London, W.1, and Messrs. Newton and Co., Ltd., of 43 Museum Street, London, W.C.1, under which the two businesses, which until twenty years ago were one, will be amalgamated. The former manufacture optical lanterns, epidiascopes, projection microscopes and similar instruments, while the latter are well known as manufacturers of lantern slides and lantern filmstrip. The combined firms will carry on business under the style of Newton and Co., Ltd., and for a short time both branches will continue at their respective addresses, after which the whole business will be transferred to the Museum Street address.

THE Coopers Hill War Memorial Prize and Medal, which was founded by members of the Royal Indian Engineering College, Coopers Hill, in commemoration of members of the College who fell during the War of 1914–18, is awarded annually by the Institution of Civil Engineers and triennially in turn by the Institution of Electrical Engineers, the School of Military Engineering, Chatham, and the School of Forestry, Oxford. The prize consists of (*a*) a bronze medal, (*b*) a parchment certificate of award, and (*c*) a money prize of the value of about £20. The triennial award falls this year to the Institution of Electrical Engineers, which has decided to invite members to submit for consideration a paper on any subject coming within the scope of electrical science or electrical engineering and their applications. Further information can be obtained from the Secretary, Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2.

DR. K. R. POPPER has pointed out a misprint in his letter "Interpretation of Nebular Red-Shifts" published in NATURE of January 13, p. 69. Formula (1) should read: "$(d\lambda/\lambda)_{T+\Delta T} = (\Delta c_T/T)_{T+\Delta T}$". Formula (7) is not very clear as printed; it should read: "$\nu_\tau = \nu_P dT_\tau/d\tau = \nu_P e^{\tau/T_P}$".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 709. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Colloidal Electrolytes

COLLOIDAL electrolytes are among the commonest of substances, probably more numerous than acids and bases. I have defined this class as electrolytes in which at least one of the ions is replaced by colloidal particles[1]. Examples are the family of soaps and the closely related sulphated compounds and the modern synthetic detergents, the bile salts, the dyes, biocolloids and many others. For no one of these solutions have we complete physical chemical information, and the various members show such characteristic differences that the following general statements serve only as a guide.

I based my conclusions that colloidal electrolytes exist upon osmotic or thermodynamic data, which were far lower than corresponded to electrical conductivity. Hence much of the latter had to be ascribed to colloidal ions. The details were naturally interpreted in terms of the then prevailing doctrine that all electrolytes were only partially dissociated.

Lottermoser[2], in 1933, showed that in extremely dilute solution alkyl sulphates followed the behaviour of completely dissociated ions. Hartley[3], in 1936, showed by transport measurements that the rather abrupt departure from this simple behaviour is accompanied by a corresponding change in transport number which occurs over a ten-fold range in concentration, and must definitely be ascribed to formation of colloid. Hartley, as I did at first, attempted to get along with only one form of colloid, but I found that this could not be reconciled with the quantitative data for conductivity, transport, and freezing point simultaneously. Hartley's further evaluation of transport numbers as "conductivities" has misled many subsequent readers. My lamellar colloid was unhappily named "neutral" to contrast it with the small, more spherical, highly charged and highly mobile ionic micelles. M. E. Laing McBain[4] showed, in 1926 and in 1935, that the lamellar micelle conducted as well as crystallized soap curd fibres; that is, about 7 per cent as well as an equivalent concentration of sodium chloride. Her diffusion data[5] give striking support to the presence of both ionic and lamellar micelles.

The existence of lamellar micelles has recently been demonstrated beyond peradventure by X-ray measurements, especially those of the collaborators of Hess and of Thiessen[6]. Stauff finds them to be *liquid* crystals consisting of double sheets of molecules in parallel array. Stauff's "*Grossmizellen*" are identical with my "neutral" or lamellar micelles. Thus it is definitely settled that there are two kinds of colloidal particles in, for example, soap solution.

Stauff[6], Hess[6] and Hartley[7] have each recently summarized the views of their respective groups. The chief remaining divergence of opinion is as to the Debye-Hückel effect of a conducting colloid particle. Hartley maintains that it has the activity and ionic effects of a highly multivalent ion. This, as Hartley shows, should effect an enormous lowering of thermodynamic activity as well as conductivity, even in great dilution. Van Rysselberghe[8] and I prefer to suggest that the charges are so far apart (16 A. according to Hartley) that their influence is as little as in solutions of uni-univalent electrolytes. This view accords with the fact that admixed electrolytes produce an additional lowering of freezing point or increase of conductivity or an electromotive force about the same as if they had been dissolved in pure water as solvent.

Meyer and van der Wyk[9] have shown how with simple assumptions it is possible to build up extensive lamellar micelles by equal steps beginning with the simplest aggregates, namely, ion-pairs, so that a proportion of all sizes will be simultaneously present. This appears especially evident when examining the freezing point and other data for the lower members of the homologous series where ion-pairs become appreciable. After a certain size, further growth of lamellar colloid has but little influence upon the properties of the solutions.

A most important and unexpected property of many colloidal electrolytes is their detergent action. For example, a dilute soap solution dissolves appreciable amounts of hexane, lowering its vapour pressure to a value far below that of free hexane. Bile salts exhibit this property of dissolving otherwise insoluble materials, essential to physiological function. Hess has shown that the X-ray spacings of the lamellar micelles expand to incorporate sheets of the hydrocarbon just as they normally contain sheets of water. Such detergent action is noticeable at concentrations far below those at which lamellar micelles are shown by X-rays and even below the critical concentration of ion association. The amounts taken up bear in general no relations to the chemical nature of detergent and substance dissolved or to ordinary solubilities.

Finally, most colloidal electrolytes, like their non-electrolytic relatives, are highly surface active. Many exhibit remarkable anomalies in surface behaviour, in some cases at a concentration below that at which micelles are recognized to form, and in others in a higher range of concentration.

I am of the opinion that in accordance with the mass law the ionic micelles begin to form in very dilute solution and steadily increase throughout parallel to the thermodynamic necessity that the concentration of simple ions likewise must increase throughout the range of stable solution. The lamellar micelles arise from ion-pairs and higher aggregates formed at the "critical concentration for micelles", increasing in size and amount until their development is sufficient to produce an X-ray pattern in the solution.

Cosmic Ray Intensities and Cyclones

In a recent note[1], we have pointed out that cosmic ray intensities in Japan show a noticeable change under different air mass conditions. In this letter we should like to direct attention to the effect of cyclones on cosmic ray intensities.

The cyclonic structure, after the Norwegian school, is shown in Fig. 1, where solid lines represent isobars. The right-hand discontinuity of the cyclone becomes a warm front, where the warm tropical air is forced to override the cold wedge of air underlying it. The left-hand portion of the cyclone becomes the cold front, where the head of cold air is displacing the warm air. In normal cases the cold front travels faster, so that it soon begins to overtake the warm front, resulting in an occlusion. In Japan proper, the air behind the cold front is generally colder than that ahead of the warm front, having had a shorter trajectory over relatively warm sea areas.

In order to see the influence of cyclones on cosmic rays, the following procedure is adopted. We choose for the present purpose thirteen typical cases of developed cyclones during the year 1937, the centres of which were determinable within a radius of about 1,100 km. (or 10° latitude) from Tokyo. Corresponding hourly means of cosmic ray intensity, 359 in number, are picked out from the data obtained with a Steinke cosmic ray meter inside 10 cm. of lead. The observed intensities are then reduced to the values at the standard pressure 755 mm. mercury using a true absorption coefficient $\mu = 9 \cdot 5 \times 10^{-3}$ cm. mercury for air.

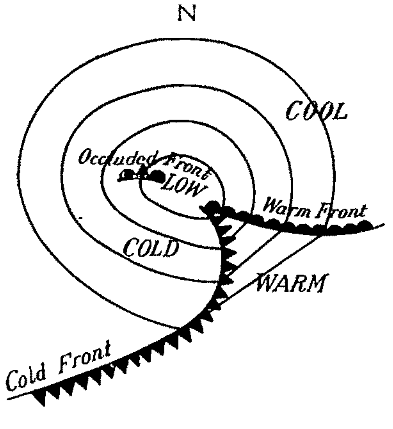

Fig. 1.

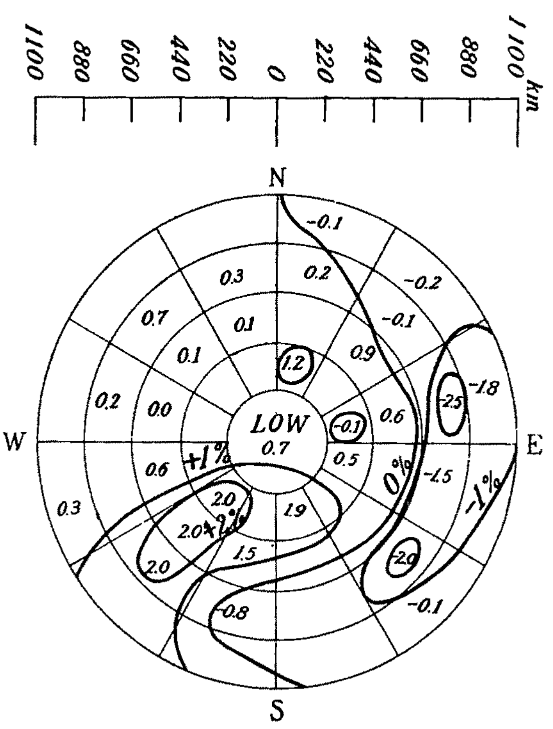

Fig. 2.

Taking the centre of the depression as the origin, we now consider the position of Tokyo relative to it, representing it on a polar diagram which is divided into 49 sections (Fig. 2). Cosmic ray intensities in Tokyo at its various relative positions from the cyclonic centre are then written down on the corresponding sections of the diagram and the average intensity is determined for each section. Fig. 2 shows the percentage difference thus obtained of each average from the mean of the total.

The diagram shows, as a general feature, that the intensity of cosmic rays is highest when Tokyo lies to the south-west, lowest when it is to the east-south-east, and intermediate when it is to the north-west of the cyclonic centre. This means, from Fig. 1, that the passage of a cold air mass tends to increase the cosmic ray intensity, while that of a warm air mass tends to decrease it. Variations of exactly the same character have been shown in our recent note[1] to take place under various air mass conditions of the year, the effect in both cases being of about the same magnitude, ±2 per cent.

Since we find low values of cosmic ray intensities in the warm-front face and high values in the cold rear as shown in Fig. 2, we can deduce the presence of active warm air overriding the thin cold wedge of air far out into the cool sector and extending high up to the upper troposphere or even to the stratosphere. It is interesting to note that cosmic ray data provide us with knowledge on the upper air conditions rather than those of the lower atmosphere.

The explanation of these results on the basis of the instability of the meson will be given elsewhere.

This work was done as a part of the programme of the Cosmic Ray Sub-Committee of the Japan Society for the Promotion of Scientific Research.

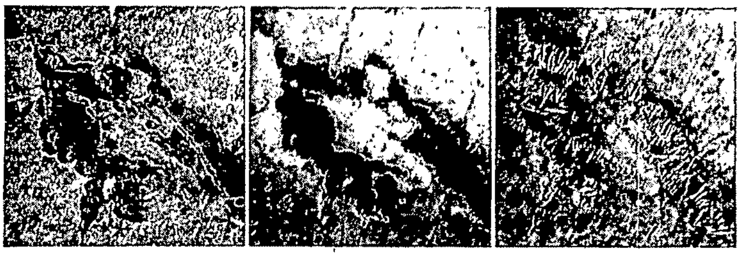
A Lead Etching Effect

The observations described below have been made in the course of the metallographical examination of some samples of ancient lead of Roman origin (*ca.* second century A.D.). These leads, hailing from Corbridge, Northumberland, and Pentre Ffwrndan, Flintshire, appear to have been left in the furnaces in which they were produced, and were evidently, at the end of furnace operations, in an oxidized condition, for they now contain patches of red litharge, which occupy blow-holes and rifts in the metal. This litharge has been isolated and its identity proved by tests and also analytically, two preparations from different sources being found to contain 95·6 and 97·7 per cent of PbO, the balance being mainly infiltrated carbonates of iron and calcium.



Micrographs of lead containing inclusions of litharge (× 25).

For etching sections of these samples, an extremely dilute solution of hydrochloric acid, at the boiling temperature, proved satisfactory, since its attack on the litharge is limited and, at the same time, the surface of the lead is cleansed by it. A striking result of this mode of operating is that the lead in contact with litharge, whether embedded in it, or surrounding an inclusion of the oxide, becomes fringed with dendrites of lead. This is illustrated in the accompanying micrographs (× 25), *A* being that of a polished surface of lead, with inclusion of litharge, *B* and *C* the same area after immersion in the etching medium for 10 and 30 seconds respectively.

At first sight, these appearances suggest that a pre-existing relationship of the two constituents, such as would arise from the solidification of the metal in a fluid lithargic medium, had been unmasked by etching; but this is obviously impossible since the freezing point of the litharge is about 600° C. above that of lead. Further, the perfection of the dendritic forms at various stages of development should be noted, which suggests continuous growth of the lead crystals during the etching process.

Such considerations led to the conclusion that the phenomenon resulted from chemical changes taking place during the etching process; and it happens that my attention had already been directed, by other observations in this field, to the fact that when lead and litharge are placed in contact, covered with water, and the water slightly acidified with one of the common acids (hydrochloric, nitric, acetic), a lead-tree is formed, the deposition of the lead being sometimes in the form of delicate dendrites, sometimes in compact masses of equiaxial crystals, among which well-shaped cubo-octahedrons can occasionally be discerned. The appearances shown by these ancient leads can be imitated perfectly by binding together a piece of sheet lead with a tablet of litharge (either cut from the massive material, or made by compressing the powder), or even with a plate of tabular cerussite, then cutting a cross-section through the two and etching in the manner described above.

These reactions are obviously related to those which have been observed on the precipitation of lead from solutions of its salts by lead itself, which result in the formation of what has been termed an autogenous lead-tree. Nearly a century ago, Wöhler[1] observed this to happen when a rod of lead was immersed in a concentrated solution either of nitrate or acetate of lead over which water was poured carefully, so that the liquids did not become mixed; precipitation then occurs on the part of the metal in the concentrated solution. There can be little doubt that the explanation of the etching effect described here is to be sought in a similar difference of concentration of the lead solution produced by the action of the etching acid on the litharge. It is remarkable that the action should be so speedy and should take place even when the specimen is held in an inverted position and moved continually to and fro.

Congenital Hyperglycæmia in Mice

Cammidge and Howard[1] have published some very remarkable results concerning the genetics of hyperglycæmia in mice. They state that their mice fell into two groups. In one of them the concentration of blood glucose, estimated by Folin and Wu's method, lay between 124 and 114 mgm. per 100 ml. In the other it lay between 88 and 74. The hyperglycæmic condition behaved as a recessive, and was not linked with albinism.

The accompanying table shows the striking fact that in each of the seven families which segregated, the observed figures agreed with the expectation to the nearest unit. The expectations in each column are given in italics immediately after the observed

Family	Coloured normal	White normal	Coloured hyper-glycæmic	White hyper-glycæmic	Probability
B	6, *5·5*	5, *5·5*	—	—	0·4512
E	—	17, *17·5*	—	18, *17·5*	0·2641
F	8, *7·75*	8, *7·75*	7, *7·75*	8, *7·75*	0·02159
G	6, *5·75*	6, *5·75*	6, *5·75*	5, *5·75*	0·03281
H	26, *26·44*	9, *8·81*	9, *8·81*	3, *2·94*	0·005179
J	18, *18*	6, *6*	6, *6*	2, *2*	0·009292
K	16, *16·9*	6, *5·6*	6, *5·6*	2, *1·9*	0·03472

results. The last column gives the probability of obtaining so good a result. As an example of the calculation, the following observations would have given as good a fit or a better one in the case of family *K*: 16, 6, 6, 2; 17, 6, 6, 1; 17, 6, 5, 2; 17, 5, 6, 2. Since the expectations are $\frac{9}{16}$, $\frac{3}{16}$, $\frac{3}{16}$ and $\frac{1}{16}$ of the total of 30, the respective probabilities are:

$$\frac{30!\,3^{44}}{16!\,6!\,6!\,2!\,16^{30}},\quad \frac{30!\,3^{46}}{17!\,6!\,6!\,1!\,16^{30}},\ \text{and}\ \frac{30!\,3^{45}}{17!\,6!\,5!\,2!\,16^{30}}$$

in the last two cases. The sum of these is 0·03472.

In all cases except the last, the fit was as good as possible. We are therefore justified in multiplying the probabilities together, and find that, for the first six families, the probability of obtaining the best possible fit is $4{\cdot}06 \times 10^{-9}$. We cannot make an estimate of the joint probability of so good a fit for all seven families without using a criterion such as χ^2, which is not wholly suitable in such cases. But it is clear that Cammidge and Howard's results cannot reasonably be explained on a basis of random sampling.

Other workers on mouse genetics, even when their totals agreed very well with expectation, have always observed a considerable amount of divergence in individual families, which was sometimes greater than that to be expected on a basis of random sampling, and never much less. The results obtained by Cammidge and Howard[2] in the case of congenital hypoglycæmia are not quite so striking, but they too are difficult to explain on the basis of sampling theory. Both sets of data would be fully explicable had the authors selected for publication out of a much larger number those data for which the agreement between theory and observation was closest. We therefore consider that, as in the case of Moewus' results, discussed by Philip and Haldane[3], those of Cammidge and Howard should not be accepted until they have been confirmed by other workers.

True and False Teleology

THERE has recently been a considerable revival of interest, largely due to the work of Darlington[1], in the teleology of different systems of reproduction. The logical status of teleological arguments is very different in this connexion from that in other spheres, since the 'purpose' which is brought forward is the fulfilment of the conditions for rapid evolutionary advance under the influence of natural selection. That is to say, a genetic system which achieves its 'purpose' provides in so doing the mechanism for its survival. The considerations which have led to the rejection of teleological arguments in other connexions therefore do not apply; though one might still question whether the teleological phraseology is the most convincing in which the arguments can be framed.

There is, however, a danger that the teleological method of argument will be carried over, by association, into regions in which it cannot be sustained. This seems to have occurred, to some extent, in the valuable article by Mather[2] in which he discusses the evolutionary significance of the formation of two different sexes in the diploid phase. He is not content to point out that the separation of the sexes is a mechanism for encouraging cross-breeding, but he contrasts this statement with some sentences, taken from a recent work of mine[3], on the developmental mechanisms involved, from which he deduces that "the sexes are separated supposedly in order to ensure that the gametes are differentiated". Such a view, he states later, must be rejected.

But such teleological statements should never arise in a discussion of developmental mechanisms. It is not sufficient to recognize that the development of two distinct sexes may be an evolutionary advantage; we have still to find out how it is done, and the "developmental-genetical idea" cannot be "dismissed". At the same time, this does not invalidate the arguments which Mather brings forward as to the evolutionary consequences of such a differentiation; in fact, he will find a statement of his main point, that the evolutionary advantage of having two distinct sexes is that it ensures cross-breeding, in the sentence immediately preceding the ones he chooses to quote. But if the new teleology is to be received with the respect which is its due, it is of the greatest importance that it should not stray outside its own legitimate fields.

[2] Mather, K., NATURE, **145**, 484 (1940).

[3] Waddington, C. H., "An Introduction to Modern Genetics". (London: Allen & Unwin, 1939.)

DR. WADDINGTON's criticisms seem to be two. In the first place, I am taken to task for the unwarrantable use of teleological expressions, particularly in the specific case of my paraphrase of his own discussion of sex separation. Inasmuch, however, as the discussion was originally Waddington's and not mine, I can scarcely be called to account for its nature, whether teleological or otherwise. In any event, the point is trivial, as I feel confident that Darlington and Waddington would agree with me in regarding adaptation as the outcome of selection and in denying that it was purposeful, whether the discussion concerned genetical or morphological questions.

Secondly, I am criticized for wishing to "dismiss" the "developmental-genetical idea". This I have no desire to do in general as, clearly, developmental studies can contribute much to our understanding of genetics. But I do disagree with the specific idea, apparently held by Waddington in common with many others, that separation of the sexes in the diploid phase is essentially a reflection of gametic differentiation. They may be related developmentally in diœcious organisms, but this should not blind us to their wholly dissimilar genetical consequences. Gametic differentiation cannot of itself lead to regular outbreeding, as is well shown by Triticum and Pisum, where the two kinds of gametes are strikingly different but where self-fertilization is the rule. On the other hand, crossing between different individuals must always follow from diœcism. As Waddington, in the section of his book which I quoted, and in the previous sentence which I did not quote, relates outbreeding primarily to gametic differentiation and thence secondarily to separation of the sexes, I must disagree with him. Differentiation of the gametes has no place in the genetical relation between outbreeding and unisexuality.

Moisture-Relation as a Determining Factor in the Transformation of the Basidia of Certain Polyporaceæ

BASIDIA of many Polyporaceæ at the end of the rainy season and during intervals between two showers of rain have been observed to be gradually transformed into hyphal elongations with terminal spores that are exactly like basidiospores. Conversely, on the advent of rain in the middle of a dry season, the hyphal elongations soon become reconverted into regular basidia.

Such conversion has been reproduced under experimental conditions. When a piece of the fruit body of a thin and desiccated specimen was placed under the running water of a laboratory tap overnight, the hyphal elongations entirely disappeared from the pore-tubes and the majority of the pore-tubes developed mature basidia with sterigmata and spores. When a piece of the same fruit-body was stuck to the lid of a moist agar-plate and examined daily under the microscope, it was found that, as the water of condensation gradually disappeared from the plate in the course of three or four days and the plate became comparatively dry (the relative humidity becoming reduced to about 85 per cent), the pore-tubes displayed a development of a large number of clamped and elongated hyphæ with terminal spores and a few abnormal elongated narrower basidia. The experiment was repeated several times and sometimes in reverse order, and in each case the same result was obtained. Such experimental conversion was quite successful with thin and easily desiccated specimens of Polyporus, Polystictus, and Hexagonia. It did not succeed well with very thick specimens of Polyporus, Dædalea, Fomes, Trametes, Lenzites, etc., as it is known that all specimens cannot withstand desiccation to the same degree.

From the experiments described above it is concluded that it is mainly the water-relation which controls the transformation of basidia into hyphal elongations with clamp-connexions and terminal spores and *vice versa*. None of the previous workers (Patouillard, Matruchot, and Heim) has correlated this change of form of basidia with the varying external conditions.

Details of the work will be published elsewhere.

Urinary Excretion of Combined Ascorbic Acid in Pulmonary Tuberculosis

IT has been shown before[1] that several plant tissues contain ascorbic acid in a combined state (ascorbigen) besides free ascorbic acid. This substance has since been considerably concentrated from cabbage[2]. The presence of combined ascorbic acid in urine was observed by Scarborough and Stewart[3] and by ourselves[4]. Evidence has been presented from this laboratory[5] which indicates that ascorbic acid may have a detoxicating action both in the normal system and also in the infected condition. Thus after the injection of diphtheria and tetanus toxins into guinea pigs, excretion of free ascorbic acid in the urine was found to be diminished, associated with an increase in the output of combined ascorbic acid. Abbasy, Hill and Harris[6] also showed that in certain infected conditions the excretion of free ascorbic acid was decreased, but the fate of the disappearing ascorbic acid is unknown. We have recently been able to investigate the relative excretion of free ascorbic acid, dehydro-ascorbic acid and combined ascorbic acid of nine normal individuals and of sixteen patients suffering from acute pulmonary tuberculosis. The mean values are given below and are expressed in terms of ascorbic acid (mgm.) excreted during a 24-hour period.

	Free ascorbic acid	Dehydro-ascorbic acid	Combined ascorbic acid	Total ascorbic acid	Combined ascorbic acid as percentage of the total
Tuberculous	5·82	3·52	8·11	17·45	42·24
Normal	44·62	7·41	15·93	67·96	23·82

A statistical analysis of the detailed individual figures, kindly carried out by Mr. K. C. Basak, gave the following results :

Difference of mean rates = 18·42
Standard error of difference = 7·56
t = 2·44

The probability of obtaining such values of t by chance alone is less than five in a hundred. The proportion of combined ascorbic acid excreted is therefore significantly higher in tuberculous patients than in normal healthy individuals.

From these results it appears first that there is a large reduction in the urinary output of total ascorbic acid in tuberculosis, and secondly that in tuberculosis there is a tendency to a relatively greater excretion of combined ascorbic acid. Apart from the simple destruction of ascorbic acid in the infected condition owing to increased metabolism, this evidence appears to support the view that ascorbic acid probably functions as a detoxicating agent, combines with certain toxins or toxic metabolites produced in the infected condition and tries to eliminate them.

Our thanks are due to Dr. B. K. Paul and his staff of the National Infirmary, Calcutta, for the facilities provided for this work.

Economic Importance of the Australian Ant, *Chalcoponera metallica*

While in Queensland during the southern winter of 1939, I took advantage of an opportunity to observe the daily activity at a number of nests of the Greenhead ant, *Chalcoponera metallica*. An analysis of the data obtained in regard to the feeding habits of this species would seem to indicate that, in southern Queensland at least, it is of very considerable economic value.

The Greenhead is a small species, the worker measuring only *circa* 8·5 mm. The colonies also are small, and are very simply organized, the nests taking the form usually of a number of irregular galleries excavated in the earth about grass-roots, or under a stone or log. The species is notable for the remarkably severe sting it can inflict, considering its small size. Observation shows that Chalcoponera is almost exclusively insectivorous like most of the Ponerinæ; the animals upon which it preys prove to be for the greater part agricultural pests. It is a significant fact that these latter are deliberately attacked and killed by Chalcoponera, several ants combining in the attack when the victim is large. In Table 1, set out below, are given the percentages by weight of the chief classes of food, the figures being the average for three colonies.

Table 1.

Larvæ. (Lepidoptera, Coleoptera, Diptera)	77·5%
Small Arachnids	11·2%
Microlepidoptera (adults)	6·8%
Other Insects (Termites, Diptera, Ants, Ichneumons, etc.)	4·5%

If the actual numbers of the insects preyed upon be tabulated, a rather different order of importance is seen, but larvæ still occupy the first place. Table 2 shows the average collection of a single colony during a working day of eleven hours.

Table 2.

Larvæ	125 per day
Small Arachnids	22 ,, ,,
Termites	16 ,, ,,
Dipterous flies	14 ,, ,,
Microlepidoptera	7 ,, ,,
Ichneumons	6 ,, ,,
Red Ants	5 ,, ,,

It is evident from the foregoing that plant-destroying insects, particularly larvæ of Lepidoptera and Coleoptera, form the bulk of the diet of this species. As these figures were obtained during the winter months they are likely to indicate a minimum rather than an average for the year as a whole; but calculation even from these winter figures shows that Chalcoponera must do an immense amount of good in the active destruction of grubs, whatever other damage to roots may be caused by the ants themselves. If these observations are typical, it would appear that a single colony of Chalcoponera, numbering only a few hundred individuals, will destroy more than 45,000 grubs in a year.

Wheeler has already pointed out that "the economic value of the Ponerinæ in tropical countries can hardly be over-estimated", largely on account of their destruction of termites[1]. He regards specialization in other insect food as exceptional in the group, citing in Africa *Platythyræa arnoldi*, which feeds mainly on small beetles, and *Plectroctena mandibularis* on millipedes and beetles[1], and in America *Lobopelta elongata* on isopods[2]. *Chalcoponera metallica* must now be added as an Australian example of this exceptional specialization.

Sulphanilamide and Glucose Antidote

The production of methæmoglobin in the blood by oxidation of hæmoglobin by sulphanilamide has been discussed by Shaffer[1], Locke and Mellon[2] and Mayer[3]. Locke and Mellon attribute the oxidizing action to the *p*-nitroso benzene sulphonamide and not to the hydroxylamine derivative. They further state that the hydroxylamine derivative is not an oxidizing agent at the *p*H of the blood, and believe that the chemotherapeutic action is due to its power of inactivating catalase (Sevag and Maiweg[4]).

In cases where there is severe oxygen-want, by the production of too much methæmoglobin and subsequent danger of damage to tissues or death, attention is directed to the fact that intravenous injection of isotonic glucose solutions immediately reduce methæmoglobin to hæmoglobin (Brooks[5]), thereby permitting the blood to carry oxygen again, and relieving the symptoms. In the case of methæmoglobin formation by sulphapyridine, the same therapy is indicated.

Effect of the Severe Frost of the Winter of 1939-40 on the Fauna of the Essex Oyster Beds

The severe frost in the winter of 1939–40, some details of which were recorded in Nature (145, 376; 1940), caused great destruction of oysters on the Thames Estuary oyster beds. Temperature readings in the Blackwater showed that the water reached 0° C. on January 1, and remained at about this level until February 19. Ice began to form on January 17, eventually forming floes which persisted for a month. Thick ice blocks were formed earlier in the shallow water of Whitstable (see accompanying illustration).

In a recent inspection (February) of the oyster beds on the Rivers Blackwater and Roach some indication has been obtained of the high rate of mortality of oysters (*O. edulis*) to date.

The entire stocks of imported Brittany oysters, all of saleable size, have been virtually lost. Sample dredgings on nine different grounds yielded in all 5,920 Brittany oysters, of which only 206 (3·5 per cent) were alive. A high percentage had died recently, as was shown by the presence of flesh in the gaping valves; in a sample count of 202 dead, 137 (68 per cent) retained dead flesh. Of those still living most were in the hockly condition, that is, not able to keep the valves tightly closed; a large number contained mud, apparently accumulated from a more or less permanent gape. A sample of 27 hockley Brittany oysters dredged on March 1 and transferred to water in dishes (at Liverpool) on the same night were all dead on March 7 except two. It seemed probable, therefore, that a small proportion of them on the beds might recover if the sea-temperature should rise high enough to permit the ciliary rejection mechanism to work satisfactorily. Dredge hauls on March 12 and 13, when the temperature had risen to 4·5° C., however, failed to yield any living Brittany oysters.

On the same rivers in localities adjoining parts of the beds where Brittany oysters were relaid, estimations were made of the mortality rates in native oysters, mostly brood and half-ware. Among 5,312 natives dredged, 2,734, or 51 per cent, were recently dead, the percentages ranging from 42 to 69. A large proportion of the dead still contained oyster meats. A striking feature was the selective mortality of the larger individuals, which had mostly succumbed. On one bed where a large stock of ware natives was stored in 5½ fathoms at low water, the mortality was as great as 58 per cent. Great losses have also occurred in the store pits, where stocks are often held for convenience at this time of the year. It is certain that there will be further additional mortality.

There can be little doubt that this heavy loss of life is due to the severe frost and its consequences. The temperature of the estuarine water fell to 0° C. by January 1, and ice began to form on the surface on January 17 during the cold period January 20–24. Thick ice blocks formed later and persisted for a month; these prevented continuous navigation, caused ships to drag or to part from their moorings, and marking beacons to be carried away or beaten down into the ground.

It is not clear what the actual cause of death is. The survival of fewer Brittany oysters on the Roach, and of fewer natives in the creeks of both rivers, suggests that the persistent low temperature and melted snow water produced their greatest effects in the shallower and more enclosed waters. Greater mortality on the inshore grounds off Whitstable is a similar phenomenon.

The probable causes are: (*a*) a gaping condition due to relaxation and paralysis of the adductor muscle as a result of a prolonged period of low temperature, for example, six weeks round about 0° C., and (*b*) great reduction in salinity at a low temperature by melted snow, causing grave disturbances in the tissues. Relaxation of the muscles permits accumulation in the mantle cavity of mud which cannot be evacuated by normal means at this temperature.

The frozen sea at Seasalter abreast of the Pollard oyster fishery, January 23, 1940. Photo by courtesy of S. D. West and Son, Whitstable.

The American slipper limpet, *Crepidula fornicata*, was weakened everywhere by the severe cold conditions. It was possible to separate six out of the ten members of a good chain with fingers weak and numb with cold. Ordinarily, separation is effected with considerable difficulty with a knife. Broken chains exhibiting the flesh of exposed individuals were common in the dredgings, and the flesh had a peculiar watery appearance. There can be little doubt that great numbers of slipper limpets will have perished. A chain of limpets from the Roach transferred on March 1 to warmer conditions in the Liverpool tank room recovered by March 7 to form a fairly strongly united chain. It is clear that a rise in temperature on the beds would quickly revive the affected limpets.

On the other hand active *Carcinus* (a few in berry), *Hyas araneus* (quite common in newly extruded berry), *Eupagurus* sp. *juv.*, *Buccinum undatum* (with abundant masses of recent spawn), *Solaster papposus juv.*, one *Asterias rubens*, *Ascidiella aspersa*, other simple Ascidians and *Alcyonidium mytili* were fresh and had apparently withstood the rigours of the winter.

Specimens of *Urosalpinx cinerea*, the American tingle, were taken and quickly began to crawl when transferred to warmer water in dishes at Liverpool. No *Purpura* or *Murex* (*Ocinebra*) were captured. In the severe weather of 1929–30 *Murex* was definitely almost annihilated[1], and *Urosalpinx* gained the ascendant; it is not clear yet to what extent, if any, the recent frost has affected *Urosalpinx*. Information may be obtainable by special dredging later in the year.

It is clear from the data that there is selective mortality among relaid oysters; the Brittany's having suffered virtual total loss and natives to the order of 50–60 per cent; also natives relaid from other rivers, for example, Kent relaid in the Roach, show a slightly higher mortality (47 per cent) on adjacent grounds than local natives (42 per cent). In the most resistant groups the mortality at the time of the survey ranged from 42 to 45 per cent.

It is clear that the stocks of oysters in the Thames Estuary are now reduced to a seriously low figure. As stocks on the Fal beds[2] are also low, English native oysters can seldom have been rarer than they now are, and the culture in as precarious a position. To improve the stocks it is probable that Government loans will be needed for the purchase of French brood and half-ware, and it is desirable that the excellent progress made by the Government in experiments on artificial production of oysters in ponds should be continued for the purpose of supplying cheap spat. It is an interesting fact that when stocks were at a very low ebb in 1935 an exceptionally good spatfall occurred in the summer of that year. Such good fortune may not always occur.

It is, moreover, highly desirable that researches be undertaken on (*a*) the effect of prolonged low temperature on the native oyster, *Ostrea edulis*, with and without varying salinity, and (*b*) the effect of deficiency of oxygen (as might occur in the store pits) in continuous low temperature. These problems have an intimate relation to successful oyster culture.

Points from Foregoing Letters

J. W. McBain surveys present knowledge of the so-called colloidal electrolytes. He believes that ionic micelles begin to form in very dilute solution and increase steadily with the concentration of simple ions; lamellar micelles arise from ions-pairs and higher aggregates, and produce X-ray patterns in the solution as soon as they have grown sufficiently large.

Y. Nishina and his collaborators of the Institute of Physical and Chemical Research, Tokyo, in association with H. Arakawa, of the Central Meteorological Observatory, Tokyo, have examined the relation of cosmic ray intensity at Tokyo to the position of developed cyclones during 1937. They find that the intensity is low in the warm front and high on the cold front. Thus cosmic ray data can give information on conditions in the upper air.

When polished surfaces of some ancient leads containing inclusions of litharge are etched with boiling, dilute hydrochloric acid, dendritic crystals of lead appear at the junction of lead and litharge and grow outwards from the lead continuously during the etching process. J. A. Smythe finds that these appearances are the result of reactions taking place during etching, whereby lead is autogenously precipitated from the solution of its salt formed by the action of the etching acid on the litharge.

Cammidge and Howard have published certain results concerning the genetics of hyperglycæmia in mice and suggest that the hyperglycæmic condition is recessive and is not linked with albinism. H. Grüneberg and J. B. S. Haldane now produce results and conclusions which indicate that the results of the former two workers should not be accepted until other workers have been able to confirm them.

S. R. Bose has succeeded in reproducing experimentally the behaviour of the basidia of many Polyporaceæ, which at the end of the rainy season and during intervals between two showers of rain gradually become transformed into hyphal elongations with terminal spores; conversely, on the advent of rain in the middle of a dry season, the hyphal elongations revert to regular basidia. Thus the author concludes that this behaviour of basidia is controlled chiefly by their water relations.

S. Banerjee, P. B. Sen and B. C. Guha have shown experimentally that in tuberculosis there is a large reduction in the urinary output of total ascorbic acid but a tendency to a relatively greater excretion of combined ascorbic acid. The ascorbic acid probably, therefore, serves as a detoxicating agent, combining with the toxins and becoming eliminated in that condition.

According to H. Barraclough Fell, it is found that the Australian ant *Chalcoponera metallica* preys principally upon larvae of Lepidoptera and Coleoptera. A single colony of a few hundred individuals can destroy more than 45,000 grubs in a year. It is thus of considerable agricultural importance.

On the Blackwater and Roach Rivers (Essex) J. H. Orton found that the whole of the stocks of imported Brittany—and more than 50 per cent of native—oysters were dead in a survey of February 29–March 1; more natives succumbed later. The causes of mortality are discussed. Temperatures about freezing point prevailed continuously for about six weeks and ice-flows were present in the estuaries for about a month. The effects of these conditions on other marine bottom fauna are noted. It is shown that oyster-culture in England is in a precarious position, that the help of the Government is needed for its recovery, and that certain researches might very well help towards more successful oyster culture.

RESEARCH ITEMS

Travellers in Tibet

A SERIES of communications by the late H. Hosten, S.J., dealing with records of Jesuit missions in India in the seventeenth and eighteenth centuries, published recently by the Royal Asiatic Society of Bengal (4, 1938, No. 4. *Letters*, 1939) includes correspondence, for the greater part unpublished, of the Jesuit missionary, Fr. Ippolito Desideri, with the authorities of his order at Rome in the years 1713–21. He left Rome at the end of September 1912, and arrived at Joa in August of the following year. On June 26, 1715, accompanied by Fr. Manoel Freyre, he arrived at Leh (Ladakh) by way of Srinagar, Kashmir. Up to this point Desideri was aware only of the existence of two Tibets, a Little Tibet (Baltistan) and Great Tibet (Bhutan). In Ladakh he heard of a third, a Great Tibet, U-Tsang, of which the capital was Lhasa. Desideri's object in visiting Tibet was to re-establish the Jesuit Mission of de Andrada (1624–1640) which he now erroneously concluded had been in Lhasa, but in fact had been in Tsaparang. Desideri reached Lhasa on March 18, 1716, but as the Capuchin Mission claimed priority there he was recalled in 1721. He returned to India and finally reached Rome on December 23, 1727. While from the point of view of evangelization his career in Tibet was a failure, he learned Tibetan, which he wrote in both prose and verse, translated Tibetan books, and may have composed, as he intended, a catechism, grammar and a dictionary for the use of the Capuchin Fathers. In addition to interesting material relating to Tibetan society, Desideri records how "this great kingdom of Great Tibet fell into the hands and power of the Tartars", an event which took place during his stay in Lhasa.

Kurds of the Rowanduz Area, Iraq

AN account of the Kurdish social organization in the Rowanduz area of Iraq by E. R. Leach (Monographs on Social Anthropology No. 3 : London School of Economics, 1940. Pp. 74+16 plates. 5*s*.), based upon evidence collected in a five weeks survey carried out in 1938, records data relating to a people and an area concerning which information is scanty. Although linguistically of 'aryan' rather then 'semitic' stock, a close correlation undoubtedly exists between Kurdish social forms and those of Arabia in general. The study, which deals with contrasting factors of cohesion and conflict that affect the lives of this small group of people, rather than with "manners and customs", in other words ethnographic facts, illustrates once more the futility of attaching psychological labels to cultural groups. Again and again the Kurds as a group have been labelled treacherous, bloodthirsty, lazy, virile, stupid and a dozen other things besides ; this study at least shows that there is no such easy classification, but that while the structural pattern of a society does impose upon individuals some standardization of behaviour, it affects the interests of individuals in widely different ways, and their resulting reactions differ accordingly. There can never be absolute conformity to the cultural norm. Until ten years ago the Rowanduz area was extremely inaccessible. Investigation was confined mainly to the Soran and Balîk tribes of the mountainous region in which poverty of soil, severity of the winter and difficulties of intercommunication between the valleys are the most prominent characteristics. Tribal organization has been much affected by contact with external authority and to-day is undergoing extremely rapid and at times violent changes.

Biology of Parasites of Teak Defoliators

IN *Indian Forest Records*, Entomology, 5, Nos. 4–6, 1939, are three papers on the above subject. P. F. Garthwaite and M. H. Desai deal with one hundred and sixteen species of parasites reared from two moths, namely, *Hapalia machaeralis* Walk., and *Hyblœa puera* Cram., the larvæ of which are common defoliators of teak trees in Burma. They include both primary parasites and hyperparasites. Of the latter, most of them are Chalcids, while the primary parasites are mainly Ichneumonoidea and Tachinidæ. Some further notes on the biology of these parasites are contributed by C. F. C. Beeson and S. N. Chatterjee. The third paper, by P. N. Chatterjee, is a detailed study of the biology and morphology of a single species of parasite, namely, the braconid *Apanteles machaeralis* Wlkn. The work embodied in these three papers is a contribution towards a knowledge of the natural controlling agencies of teak defoliators. This survey of the parasites aims at assessing the value of each species, with the ultimate object of examining whatever possibilities there may be of increasing any desirable species by sylvicultural and biological methods. The two moths referred to are the most important of the teak defoliators. Each passes through thirteen or fourteen generations in a single year, and control by other than biological means is stated to be impracticable. Considerable difficulty has been experienced in getting the parasites identified owing to the great paucity of specialists in the groups concerned. The result has been that only thirty-three out of the one hundred and sixteen species dealt with had been named at the time of publication.

Japanese Gephyrea

UNTIL 1904 only four species of Gephyrea had been recorded from Japan, but in that year Ikeda brought the number up to thirty-seven, twenty-four of which were new. As the result of the examination of three collections, twenty-three species from Formosa, eight species from the Riukiu Islands and fifteen species from Korea, Hayao Satô (*Sci. Rep. Tôhoku Imp. Univ.*, 14 ; 1939) has been able to add eight new species. This brings the total number of Gephyrea now known from Japan and Korea up to ninety. The author not only describes the new species, but also makes it an opportunity for reviewing the whole of the group in Japanese seas. The paper thus provides a most useful survey of our present knowledge, and is furnished with full keys to groups, genera and species. It is provided with five plates illustrating by photographs many of the species. There are also a large number of text-figures.

Amphipod Bathyporeia in Tow-nettings

E. Emrys Watkin has studied the migrations of four species of Bathyporeia at Millport (*J. Marine Biol. Assoc.*, 23; 1939). The species represented live in a sandy bay, burrowing an inch or less into the sand between tide marks. A distinct zoning was found from high-tide mark to low-tide mark. *Bathyporeia pilosa* occurs above the high-water mark of neap tides, *B. pelagica* is a mid-tidal form and *B. elegans* a low-water form. The latter, together with *B. guilliamsoniana*, extends beyond low-water mark. Tow-nettings taken at night over the same area show that these amphipods come out of the sand and swim about, although none is taken in the daytime. The same zoning of the species occurs. The reasons for these migrations are by no means clear, but in his detailed discussion the author suggests that the nocturnal vertical movements into the waters of the tidal flow may be determined, in part, by the influence of the tides, which has some relation to the double breeding cycle in each month. These problems require much further investigation.

Temperature of Grain Heaps

A method of storing grain in Egypt, that has persisted from the times of Ancient Egypt, is the 'shouna' system, in which various types of grain are simply exposed in heaps in the open on a small piece of enclosed land. The method is particularly utilized by banks and money-lenders, part of the value of the grain having been borrowed against this security. Such heaps are built up of most various samples and must be contaminated by pests; the question then arises whether the pests will multiply in the grain under such storage conditions. The possibility has been stressed by Willcocks that under Egyptian conditions hard dry grain in well-ventilated conditions which permit of the powerful drying action of the sun may prove the most practicable method of controlling pests. Rizk Attia has, therefore, recently published (*Bull.* No. 192, Technical and Scientific Service, Cairo, 1939) a very full study of temperature distribution in such a heap of stored grain, associated with studies of pest distribution in the grain heap. The kind of grain and especially its colour will modify the range of temperatures, which rise generally in the sun, though loss of water from the heap may produce a considerable cooling effect. All factors found to affect the temperature are tabulated and they are numerous, but in general the results show a marked fall in the number of pests in the deeper layers of an unstirred heap, and especially species of Calandra seemed to be kept under, as the result of the high temperatures, in heaps stored in the sun. In general, wheat at humidities higher than 32 per cent will absorb water and increase in weight; at lower humidity it usually loses water.

The 'Rhizosphere'

Under this term A. G. Lochhead, Dominion agricultural bacteriologist, includes the soil in the immediate neighbourhood of a growing root system, and in a series of recent papers (*Canadian J. Res.*, 16, 152–161; 1938: 16, 162–173; 1938: 18, 42–53; 1940) he has examined the influence of the root system upon the bacterial flora. In the rhizosphere gram-negative rods are proportionately increased, gram-positive rods, coccoid rods and spore-forming types less abundant. In the rhizosphere there is a notably greater proportion of motile forms and a pronounced increase in chromogenic types, also a higher incidence of liquefying bacteria and of those fermenting glucose. To date, Mr. Lochhead concludes that his results suggest that plant varieties resistant to soil infection may exhibit a more selective action through root excretions upon the saprophytic soil microflora.

Origin of Maize

P. C. Mangelsdorf and R. G. Reeves (*Bull.*, 574, Texas Agric. Exp. Stat.) provide a fascinating story concerning the origin of maize. This thorough and penetrating analysis of the taxonomy, history, archæology, genetics and cytology of the Maydeæ summarizes the previous work on the subject and puts forward a novel theory of the origin of maize. Zea is definitely of New World origin, and is closely related to Tripsacum and Euchlæna. It had been assumed either that these three genera are segregates of a large aggregation or that Zea arose from Euchlæna. The authors bring forward the view that maize arose from a wild Amazonian progenitor, and was brought into domestication in the Andes. The secondary large distribution centre is Mexico and is believed by the authors to have arisen from crossing between Euchlæna and Zea. The most interesting hypothesis is that wild Euchlæna arose originally from crosses between wild Tripsacum and cultivated Zea. The wealth of data derived from actual cytogenetical experiments, taxonomy and history make this theory highly plausible. If one prefers to follow the older theory that maize originated from wild Euchlæna, this well-designed monograph still provides a standard source of reference on the origin of maize.

Exchange between a Metal and its Ions in Solution

In experiments with radioactive lead, Hevesy and Biltz in 1929 showed that there is an exchange of atoms between metallic lead and a solution of a lead salt: in an hour, the quantity of lead exchanged corresponded with a depth of about a thousand atomic layers in the metal. B. V. Rollin (*J. Amer. Chem. Soc.*, 62, 86; 1940) has prepared radioactive silver ^{106}Ag by bombarding palladium with deuterons, using a cyclotron. By treating a silver plate with a solution of the radioactive silver nitrate, it acquired an activity corresponding with an exchange with the solution of about 150 atomic layers after some hours. Sheets of gold and platinum also acquired an activity corresponding with about 100 atomic layers. When an active silver surface was shaken with silver nitrate solution, an exchange of silver corresponding with ten atomic layers was found in two hours. The exchange was increased by a factor of ten if the surface was pretreated with sodium nitrate solution, which may be due to some kind of activation of points on the surface of the silver by sodium ions.

Separation of Isotopes

The method of Clusius and Dickel for the separation of gases of different molecular weights, and particularly isotopes, using simultaneous thermo-diffusion and convection, has proved of considerable value in the separation of mixtures of gaseous isotopes into light and heavy fractions. In its simplest form the apparatus consists of a long vertical tube, cooled on the outside, along the axis of which passes an electrically heated wire. The apparatus was used by Clusius and Dickel to alter the isotopic composition of chlorine, ^{35}Cl : ^{37}Cl, from

77 : 23 to 0·6 : 99·4. Many light elements contain very small concentrations of isotopes which are of interest from the point of view of nuclear physics, and their enrichment is therefore a matter of some importance. R. Fleischmann (*Phys. Z.*, 41, 14; 1940) reports experiments carried out with nitrogen. With two separation tubes of 9 mm. and 11 mm. diameter and 12 m. long, 770 c.c. of gas containing 9·2 per cent of $^{14}N^{15}N$ were obtained in six weeks, and from this, 110 c.c. of gas containing 18 per cent of $^{14}N^{15}N$ were obtained. The band spectra of the products indicated that separation had occurred. W. Groth and P. Harteck (*Naturwiss.*, 28, 47; 1940) have recently carried out separation experiments with krypton using an apparatus of a similar type. After 5–8 days separation, the atomic weight of the krypton was 1·51 units less than normal, and after 9–14 days it was 1·74 units less. The large amount of work done on isotopes is reflected in an article by O. Hahn, S. Flügge and J. Mattauch, appearing in a recent issue of *Phys. Z.* (41, 1; 1940). It includes a table giving all relevant data for each element up to the end of 1939. The isotopic weights, and relative abundance of all known isotopes, together with packing fractions and mass defects, and the chemical atomic weight calculated from the isotopic composition of each element, are given. The maximum abundance of isotopes at present undetected is also given.

High Temperature Photolysis of Acetaldehyde

G. K. Rollefson and D. C. Grahame (*J. Chem. Phys.*, 8, 98; 1940) report that the mechanism of the photolysis of acetaldehyde vapour is almost identical with that put forward to explain the thermal decomposition of acetaldehyde. Photolysis was carried out by 3130 A. and 2652 A. mercury radiation at 96°–350° and by 3303 A. at 60°–300°. The mechanism, by which methyl and formyl free radicals are formed and through them further decomposition of acetaldehyde is brought about, can be represented as: (i) $CH_3CHO + h\nu \rightarrow CH_4 + CO$; (ii) $CH_3CHO + h\nu \rightarrow CH_3 + CHO$; (iii) $CH_3 + CH_3CHO \rightarrow CH_4 + CH_3CO$; (iv) $CH_3CO \rightarrow CH_3 + CO$; (v) $CHO \rightarrow CO + H$; (vi) $CH_3CHO + H \rightarrow CH_3CO + H_2$; (vii) $CH_3 + CH_3 \rightarrow C_2H_6$. Photolysis of the mixed vapours of acetaldehyde and acetone at 200° and 300° has also been studied. At 3130 A. more free radicals are produced from acetaldehyde than from acetone, whilst at 2652 A. acetone yields more free radicals than acetaldehyde. Neither acetone nor acetaldehyde shows any afterglow $\frac{1}{400}$ sec. after irradiation with 3130 A., indicating either that their fluorescence does not arise from recombination of acetyl radicals (that is, from activated diacetyl molecules) or that the life-time of acetyl radicals is less than $\frac{1}{400}$ sec.

A New Ionization Gauge

THE requirements of an ionization gauge to measure pressures of the order 10^{-8} mm. of mercury are: a wide connecting tube, ease of removing occluded gas, electrical leakage to the plate small, and reasonably high sensitivity. R. S. Morse and R. M. Bowie, of Distillation Products, New York, claim that their new gauge fulfils these demands more thoroughly than any gauge previously described (*Rev. Sci. Inst.*, March 1940). The bulb of the gauge is 5·5 cm. in diameter, of Pyrex glass, with an exit tube of 1·6 cm. diameter. The plate or collector is a platinum film deposited on the inner wall and is connected to an outside deposited ring by a fine wire embedded in the glass. The grid is a double wound spiral of tungsten wire, each end having a terminal. The filament is pure tungsten. Owing to the large volume between grid and plate and the open form of the grid, the sensitivity is higher than usual. Below pressures of 10^{-4} mm. the plate current is found by comparison with a McLeod gauge to be proportional to the pressure. The best working conditions are 3·5 volts for the filament, 150 for the grid and −25 for the plate.

New Method in Quantum Mechanics

A NEW method for determining eigenvalues and eigenfunctions has recently been developed by E. Schrödinger (*Proc. Roy. Irish Acad.*, A, 46, 9; 1940), which, he considers, gives the most direct insight into the way the line spectrum depends on the structure of the wave equation. This method avoids cumbersome transformations and expansion in power series, using instead the factorization of the second order operator occurring in the wave equation into two mutually adjoint operators of the first order. For the problem of Planck's oscillator, it gives one eigenfunction by integration of a very simple differential equation, and then derives all the other eigenfunctions and their corresponding eigenvalues by application of a differential operator of the first order. Prof. Schrödinger also applies the method to the Kepler motion of the hydrogen atom, and also to Kepler motion "in the hypersphere" (that is taking account of the curvature of the universe). This last problem is a new one, which appears difficult when treated by any other method. It has some interesting features, such as the obliteration of the sharp distinction between elliptic and hyperbolic orbits, and the resolution of the continuous spectrum into an intensely crowded line spectrum.

Solar Eclipse of October 1, 1940

A COMMUNICATION from the U.S. Naval Observatory, Washington, D.C., published as a supplement to the American Ephemeris of 1940, gives much useful information concerning the total eclipse of the sun on October 1. The booklet is designed especially for use along the paths of totality in South America and South Africa; but the entire region covered by the eclipse on both continents is indicated on two large-scale maps (c. 150 miles to the inch) contained in a pocket on the cover. Red lines overprinted on these maps show the times of beginning and ending of the eclipse at 5- or 10-minute intervals, so that even for points not in the path of totality the times of beginning and ending of the partial phase can be estimated to a fraction of a minute. Data are given dealing with the meteorological conditions that prevail in or near the paths of totality, and the most favourable locations for observing the eclipse are suggested. In addition to the usual astronomical data, eight pages are devoted to the convenience of those who plan to make ionospheric observations during the partial and total phases, for the purpose of testing various hypotheses underlying the theory of origin of the *E* region of the ionosphere. In an appendix are reprinted special temperature, rainfall, and cloudiness data compiled from volunteers' observations made within the African totality belt at 3, 4, and 5 p.m. local time during September and October for a period of five years since September 1933.

FOREST MANAGEMENT AND EROSION

By Prof. E. P. Stebbing,
University of Edinburgh

THE criticism has been made that Government administration annual reports from overseas often appear so belatedly that their perusal bears little relation to the probable actual position at the time. Two annual reports of the Forest Administration of Nigeria for the years 1937 and 1938 were published in 1939 (Sessional Papers Nos. 3 and 34: Government Printer, Lagos). Nigeria has been notorious for the delay in appearance of her forestry reports. That such delays are not insuperable would appear from the fact that the report for 1938 is dated by the writer February 27, 1939, and is published in the same year!

Although a chance, it is perhaps of some significance that these two annual reports should have appeared so opportunely within a short space of time; for taken together they may well be said to mark an epoch in the history of the progress (or in some cases want of progress) of forestry administration in that country. Both reports were written by the acting chief conservator of forests, an officer with long acquaintance of Nigeria, and especially of the northern regions. A vast improvement of form is achieved by the relegation of statistics to appendixes.

As the chief conservator says, the year 1937 was marked by several events of considerable importance. Early in the year the Anglo-French Forestry Commission completed its investigation of desiccating conditions in the Northern Provinces and the French territories beyond on the edge of the Sahara. Its report did not fulfil the high hopes which had been placed upon the Commission, whose investigations were unfortunately of too hurried a nature to afford material of great practical value. In the following July the Nigerian Government convened a Conference which met in Lagos, consisting of high officials representing several Departments, the object being to examine and make recommendations on the future policy of the Forestry Department. Great hopes were placed on the resolutions of the Conference, and 1938 opened out with very great promise for the Department. The optimism was, however, soon quenched. Once again, as so often before, a depressed financial situation at once reacted on the Forestry Department, the prospective increases were withdrawn, and the basic funds at the Department's disposal had, says the report, "necessarily to be reduced".

The reports throw into a strong light what has often been pointed out, the vacillating methods upon which forestry administration has been carried on by the Governments of Colonies. In 1937, as a result of a conference at which some of the highest members of the administration were present, a forest policy was determined upon and provision made to put it into force the following year. Almost before the ink of the attached signatures was dry, funds were withdrawn and once again stagnation was to supervene.

That in the interests of the country as a whole, continuity of the work of the Forest Department should be maintained, is illustrated by the following remarks in the 1937 report:

"The general examination of forests by field officers has revealed the immense importance and urgent necessity of planning. The continued and universal damage to unreserved forest and the indiscriminate encroachment in reserves emphasise the necessity of distributing the available staff to the best advantage. . . . Reservation and consolidation of the existing reserves must, of course, take first place. . . . In areas where reservation has not yet reached the required percentage and where cocoa is a popular crop, planning is all the more necessary. Many such areas are unfitted climatically to maintain cocoa as a permanent crop and the wildly unbalanced expansion which takes place after a boom must not only lead to disaster in the area itself but must also have repercussions in adjacent climatic 'tension' areas."

In his 1938 report the acting chief conservator writes that "Reservation, management and research; each must play its part"; but adds, after stating that forest reserves established must as soon as possible be placed under some form of management, "no unavoidable delays can be permitted to stand in the way of building up the total of reserved forest required".

The acting chief conservator does not appear to have quite made up his mind as to whether the most important of the duties of the Department at the present time are "to secure the existing forest estate" or the "building up of the total reserved forest required". He rightly says that no great progress in forest management can be made until the necessary percentage of forest estate is secured, and continues: "It is nevertheless equally necessary, because of the limited area of merchantable forest in Nigeria, to place under management such a proportion of this area as has been secured, without diverting to the purpose an undue proportion of the staff or funds available. Comparisons, invidious sometimes, are made with India and other Colonies in the matter of relative progress in the different branches of the Forest Department, but there is no real analogy. Our merchantable forest wealth, which is an Imperial asset as much as a Nigerian one, must be put under management as soon as possible and cannot wait for the completion of the whole framework of reservation throughout the country, a task which may take anything from fifty to eighty years at the present rate of progress."

Why? Is this logical? How much of the forests of these proposed future reserves will remain, and what will be the condition of the area left (and that of the surrounding countryside) at the end of this period of 50–80 years?

As to this comparison with India and Burma, the Burma teak forests were very much of an Imperial asset when the late Sir Dietrich Brandis began, as soon as he joined in Pegu, his enumeration surveys to ascertain the stocking. By this work he was able to maintain the continuity of supply to the European and Indian markets, which was imperative, whilst at once putting an end to unchecked fellings. But this work did not hold up forest reservation either in India or Burma. By the end of the century, a period of little more than thirty years, the framework of reservation throughout Indian and accessible Burmese forests had been accomplished, whilst considerable management had been introduced into the forests. The pity is that after about the same number of years of forestry in Nigeria the Forestry Department should have much forest reservation still to be undertaken, owing to the fact that its real position in the Administration has never until recently been understood, save to be regarded primarily as a revenue producer.

Perhaps one of the most important and progressive pieces of work the Department has undertaken during the last few years has been an outcome of the Anglo-French Commission, on the British side. Two special anti-desiccation and vegetational survey teams were appointed to carry out desiccation investigations in the Northern Sokoto, Katsina, and Kano Provinces. A special report on the Sokoto area has produced, says the chief conservator, "a very interesting set of conclusions, which are briefly that 'desiccation' in Sokoto in the form of encroachment of the Sahara is not apparent, but that all the conditions present are due to the activities of man and of domestic animals". If the writer will study the history of parts of the south-west Sahara, he will find, to quote one instance, that the howling Desert of Mauretania, situated some 400 kilometres to the west of Timbuctoo, was the centre of the great Empire of Ghana from the ninth until the eleventh centuries, when the region consisted of smiling fertile lands. It now forms part of the Sahara. The great desert did not advance over the area in sand-waves. As the writer says above, "the activities of man and domestic animals" gradually produced the result, and the region was added to the Sahara; just as the areas comprised in Sokoto and Katsina, if the present-day activities continued unchecked in the two provinces, would infallibly be added to the great desert, which would have thus 'encroached' on the area.

Members of the Society of American Foresters met in San Francisco last November. Charles A. Connaughton, of the U.S. Forest Service, discussed (Science Service, Nov. 21, 1939) problems of watershed control; they were difficult, he pointed out, because owners of watershed areas seldom receive the benefits of control measures, which cost money and labour on the spot but go mainly for the help of lands farther downstream! . . . He continued: "Rangeland research is needed for the solution of problems arising out of overgrazing, which not only brings about the displacement of good forage species by weeds but even the destruction of the soil itself through erosion. Research now in hand has already suggested that native grasses and other plants, rather than exotics, may be the best for rangeland restoration, but more research is needed to arrive at really definite conclusions. Another possible result of researches now in progress is the upsetting of the old idea, accepted almost as an axiom, that livestock and larger game animals cannot use the same range without robbing each other. Apparently, both livestock and wildlife can be produced without serious conflict on most ranges."

The forestry remedial measures (given in the 1938 Nigerian report) to be put into force in Sokoto are excellent, and indicate that this serious problem is now to be tackled with understanding; and, unlike the American rangeland and watershed problem (though Africa has the same elsewhere), the amelioration work to be undertaken in Sokoto, and extended eastward, will benefit alike the people within the area and others situated to the south.

In the Forest Report for Palestine for the period 1936–39 (Printing and Stationery Office, Jerusalem, 1939), it is stated that the total land area is some 10,000 square miles; the hills are mostly composed of limestones, with basalt intrusions in the north-east, whilst the plains are deeply covered with alluvium. The climatic desert accounts for something less than half the area; of the remainder, 45 per cent are plains and 55 per cent hilly country. The state of the hills is considered to be unsatisfactory, as most of the surface is eroded, and probably less than 1 per cent is agricultural land in good condition. The hills, it is said, were undoubtedly once covered with soil and forest, whereas they are now an artificial desert due to overgrazing. The river valleys are desolated by floods and the deposition of infertile detritus, the river beds are choked, and road and railway embankments and bridges frequently damaged.

The Forest Department, formed only in 1936, owing to the outbreaks and unrest which supervened so soon after, has scarcely had time to get well into the saddle. Moreover, promised grants were withdrawn, inevitably, perhaps, owing to the unrest. But the Department has already been able to contribute some valuable information on the subject of erosion in the Middle East. On the question of reservation of land areas for afforestation the report states: "In the course of time previous to 1936, the natural vegetation was cleared from nearly all the fertile areas of Palestine, and such vestiges as remained were on the most rocky and barren land. Even there the vegetation was almost ruined by excessive grazing and uncontrolled cutting. In consequence, the present value of the vegetation and of the land on which it stands is very low, and most of the Forest Reserves cannot be made highly productive without many years of careful management. Closure and protection, however, will very early result in the checking of erosion and flooding, and are therefore of the utmost value."

Man's old habits—fire and excessive grazing—have probably been the chief two causes for the present condition of so much of Palestine. On the subject of fire, the report says that the climate of the country, with its long summer drought, atmospheric desiccation, and dry, hot winds, is very conducive to forest fires, which would be more serious but for the sparseness of the vegetation in most places—which tells its own tale as to the downgrade of the country as a home for man, or even for his goats. The present position of grazing shows the determining factor in this latter question. The following paragraph might have been written of other areas within the British Empire; but here it possesses its own significance: "Except for the well-bred cows on a few modern dairy farms which grow fodder in irrigated fields, the grazing animals of Palestine have to depend on the grass, shrubs, and young trees which Nature provides on uncultivated land. Their only change of diet is the stubble on the cereal lands after harvest. Centuries of such treatment have produced a tough and agile goat which can consume organic matter of almost any type. The sheep, mostly of the fat-tailed breed, are also very hardy. The camel, fortunately less common in the northern districts, eats what the goat cannot reach. No attempts have been made to estimate the permanent carrying capacity of the land, the number of animals grazed is limited only by drought, starvation and disease; and the vegetation is destroyed over large areas, which have become artificial deserts in spite of good climatic and geological factors. Soils were nearly everywhere excellent before they were removed by erosion. All other forms of damage fade into insignificance beside the destruction caused by grazing, though the process is accelerated by cutting and uprooting."

Yet there are still some who dispute that obvious factor on the globe, the man-made desert—both of the past, and those of more modern origin, and in the making.

Forestry problems of increasing magnitude and importance are many in the British Colonial Empire.

The welcome and wide-visioned Colonial policy recently announced by the Secretary of State offers, it may be hoped, opportunity that in the future continuity in a forest policy, duly drawn up and sanctioned, may be persisted in, whatever vicissitudes befall the Colonial budget; and, above all, that recognition should be accorded to the factor that the scheme for reservation of the forest areas in any Colony considered needful to its economic progress, the protection of its water supplies, etc., upon which the agricultural prosperity depends, should take precedence of other work. The policy, as laid down for Nigeria by the 1937 Committee, that foreshadowed in the Palestine Report, and those so often voiced for other Colonies, should now become practical politics in view of Mr. Malcolm Macdonald's masterly White Paper.

ECONOMIC PROBLEMS OF INDUSTRIAL SCIENTISTS

A SERIES of regional conferences to discuss the economic problems of men of science and engineers employed in industry has recently been held in London, Liverpool and Manchester. Others are to follow, and it is intended that a national conference shall be held in the autumn in order to collate the information obtained at the regional conferences. The conferences are being organized by the Association of Scientific Workers, but many members of other professional organizations attended the meetings and took part in the papers and discussions. It is hoped that this collaboration will continue and increase as a result of the interest aroused.

The London regional conference, held on March 9, with Prof. F. G. Donnan in the chair, was opened by Mr. Hugh N. Linstead, with a general discussion on the place of the scientific worker in industry and on the role of professional organizations. He pointed out that, in view of the great importance of the role of the scientist in modern industry, the discrepancies between the salaries of scientists in industry as compared with those in administrative positions can only be rectified by scientists organizing themselves. Such an organization must protect the interests of the scientific worker, but be broad enough to consider the problems of the industry and the employer as well. In spite of the prejudice against trade unionism among professional workers, the trade unions play an essential part in industry, and both the scientist and the community suffer from lack of this type of organization among scientists.

This was followed by a paper by Mr. J. Stewart Cook on the question of salaries, increments, overtime, etc. His paper consisted of a factual analysis of the data available in these questions as they affect both graduate scientists and assistants, and was based on the results of a questionnaire sent out by the Association of Scientific Workers, and on data published by the Institute of Chemistry. He considers that salaries will only be uniformly adequate and satisfactory when scientists are organized on such a basis that they can and will refuse to take jobs below prescribed rates. He pointed to the good record of the British Association of Chemists in this respect, attributing its success to the policy of maintaining an appointments board, backed up by an unemployment scheme.

The rights of publication were discussed by Mr. H. T. Rhodes, and the question of holidays and opportunities for study by Mr. J. L. Pinder. The latter stressed the necessity for adequate holidays and opportunities to attend scientific lectures, if the scientist is to produce his best work. He is in favour of a 5-day week. The question of adequate time for study as well as for recreation is essential for assistants studying for degrees. He considers their position in this respect is often unsatisfactory.

The problems of the assistant were dealt with by Mr. R. Peter, himself an assistant. The assistant is faced with the double task of satisfying the employer by day and the examiner by night. The principal requirements of assistants are (1) standardization of working hours throughout industry, (2) standardization of wages based on some grading system of age and qualifications, (3) a definition of work expected on engagement and a limitation of this, in general, to technical matters, (4) allowance of adequate time for study and recreation and provision of financial assistance where necessary for the cost of study.

A paper was then given by Mr. F. W. Adams dealing with the legal side of scientific employment, in which he discussed the questions of contracts, of copyright and the right to seek alternative employment.

Prof. J. D. Bernal, in summing up, pointed out the similarities and the differences in the position of scientists in this War and that of 1914–18. Since 1918 the scientist and the laboratory have become an integral part of industry, but there has not been the development of organization of scientists which has occurred in other spheres of industry. Bad conditions for scientists mean a depression in productivity of industry. The increasing number of assistants entering the ranks of qualified scientists means that the whole range of the problem from assistant to directorate must be tackled, as an anomaly in any one section would be felt by all other sections of industrial scientists, and also by academic and Government employees. He considers that scientists as salaried workers require some type of trade union organization which would include organization of assistants. The details of such an organization would require special study, but the immediate consideration is the building up of organizations such as the Association of Scientific Workers and the British Association of Chemists.

The Liverpool Conference was held on March 4, and was opened by Mr. J. P. Lawrie with a general discussion of the questions involved. This was followed by a factual paper on assistants, their status and problems. A survey of contemporary professional organizations was then given. It was pointed out that a very large number of professional workers, such as teachers, medical men and journalists, are already organized in trade unions. In purely scientific fields the degree of organization is comparatively very low. The learned societies are precluded by their charters from activities affecting the economic conditions of their members, and the field is still open for vast development. The British Association of Chemists, with 2,000 members, has been registered as a trade union since 1920. The Association of Scientific Workers, with 1,500 members, is not now a trade union, but interests itself in economic activities. Mr. Lawrie then gave a survey of advertisements for scientific posts and a statistical analysis of the material collected regarding salaries was given. The position of women scientists was considered and the discrepancy in wages pointed out. It is realized that this question has increased in importance since the War began.

The Manchester Conference was held on March 16, with Prof. Willis Jackson in the chair. Prof. H. Levy, in opening the discussion, said that scientists are not brought up in an industrial atmosphere, and the idea of trade unionism is, consequently, foreign to them. He showed that the same forces operate with industrial scientists as with manual workers. He then analysed the different types of scientific work and discussed the impact of the War on science and on scientists. This was followed by a paper on basic salaries, increments, cost of living adjustments, etc. The question of contracts was the subject of the next paper, and the anomalies and lack of standardization was pointed out. After this, the problems of students were discussed, especially under the conditions of the War. The effect of conscription and the increase in the cost of living due to the evacuation of universities were dealt with.

The final papers dealt with the rights of publication and the problems of the laboratory assistant. In the latter, the main problems were considered to be: diversity of labour, lack of standardization, salaries, absence of status, promotion and unskilled labour, especially since the outbreak of war.

All three conferences were very well attended and were accompanied by lively discussion from the floor. The two salient features of the conferences were the realization of the growing role which the laboratory assistant takes in industrial science, and the feeling that the War is raising acute economic problems for scientists and an active organization is needed capable of protecting their interests.

A full report of the conferences will be given in the April–May number of the *Scientific Worker*, the organ of the Association of Scientific Workers.

DRUG STANDARDS FOR INDIA

THE ambition of those enlightened practitioners of medicine in India who, under the leadership of Dr. Chopra, have sought for many years past to bring that country into line with the rest of the civilized world in the matter of standardized drugs now seems to be near achievement. A comprehensive measure providing for the uniform control of the manufacture and sale of drugs as well as the importation of drugs is now before the Legislative Assembly; the introduction of such a Bill is, in itself, no small advance towards the desired goal, since the Bill is backed by resolutions from every one of the provincial legislatures empowering the central authority to pass an Act to regulate the manufacture, distribution and sale of drugs throughout India. No such resolutions were necessary for the purpose of a measure to regulate the importation of drugs, but such limited control would fail to bring about the desired purpose, namely, to create a clean business in medical supplies in every province. It would be of little use to prohibit the importation of inferior drugs if there were no means of preventing the sophistication of imports or the domestic production of inferior preparations. The Bill, when it becomes law, will extend to the whole of India.

So far as imports are concerned, the Bill makes it an offence to import misbranded drugs, by which term is meant, briefly, drugs different from what they are represented to be by the labels on their containers. It specifically prohibits the importation of "any drug which is not of standard quality", and it is interesting to find that the standards with which compliance will be necessary are as follows: (1) proprietary medicines: the list of ingredients described on the label or the formula disclosed to the Central Drug Laboratory, as the case may be; (2) vaccines, sera, toxins and other biological products of a like nature: the standards maintained at the National Institute for Medical Research, London; (3) vitamins, hormones and analogous products: the standards maintained at the National Institute; (4) other drugs: the standards of identity, purity and strength specified in the latest edition either of the British Pharmacopœia or the British Pharmaceutical Codex or any other prescribed pharmacopœia, or adopted by the Permanent Commission on Biological Standardisation of the League of Nations. On the principle of what is "sauce for the goose is sauce for the gander", the part of the Bill which relates to domestic manufacture and to the sale and distribution of drugs is in effect the same as that which applies to the importation of drugs; the standards to be complied with are identical in each case.

IRRIGATION THROUGH THE AGES

On February 16, Mr. E. Bruce Ball, president of the Institution of Mechanical Engineers, delivered an address in the course of which he surveyed "The Influence of the Mechanical Mind on the Development of Irrigation through the Ages".

From the dawn of civilization there is evidence of the activity of the mechanical mind in devising means of watering those tracts of land which could in this way be made highly fertile. Something here might have been said of the skill with which these unlettered people constructed the small channels by which the water was distributed to the fields.

The mechanical devices were introduced at the points at which the water was raised from some stream or well into the basins which supplied the system of channels. The earliest of those was probably what is known as the 'basket scoop', a hemispherical vessel operated by two men by means of two ropes each so that it could be swung up with its load of water and tilted to discharge it. The method is still in use in India and China and gives a lift of about 3 feet. The need for higher lifts and for making better use of available labour led to developments showing great ingenuity in the application of the only available material, timber. The hollowed tree trunk nicely balanced so as to enable one man to operate it, and the moving counterpoise on a balanced beam showed a keen appreciation of mechanical principles. Further improvements on these designs gave increased lift, or effected a saving of energy—no doubt that of the user himself—or again added a simple automatic device to discharge the water when it had reached its full lift or, as in another case, made use of gravity by means of a sloping path to assist tractive effort.

All these methods gave intermittent deliveries—a bucketful at a time—and we then see an important development in the production of a crude wheel carrying a number of buckets and giving an almost continuous delivery. Operated by an ox or a camel through a rough and ready form of gearing, this shows the conception of the machine being evolved. Several illustrations of different pumping or water lifting machines were shown, including one of the gigantic wheel on the Yellow River, and portable link chain pumps. While these and even the most primitive methods of irrigation can still be seen in use in many parts of Asia, and appear but puny efforts as compared with the great engineering works of to-day, it must be borne in mind that the latter have only been made possible by the new materials of construction now available and the machines and power units at the disposal of the great constructors of recent times.

Examples of the great barrages were referred to and illustrations of them and of the machinery essential to their operation shown. The different types of sluice gates and shutters and the system by which the waters are controlled were explained, thus showing how the mechanical mind has harnessed the waters to the purpose of assisting Nature to maintain the population of the world; and although much has been done there are vast resources still awaiting development. Mr. Bruce Ball claims this as but a single illustration of the dependence of human life on the creative work of the mechanical engineer.

SEVENTY YEARS AGO

Nature, vol. 2, May 5, 1870

First Number of the Second Volume of Nature

Sir Norman Lockyer, founder and editor, opens No. 27 of this journal with a short article referring to the achievements of the past six months. He remarks on the encouragement, and criticism, which he has received. "It has been our endeavour to carry out our programme by making the journal useful to workers in science; worthy therefore of their perusal, and therefore, again, worthy of their contributions: and by thus extending our appeal beyond the limits of the scientific world on the one hand, and endeavouring to keep up the dignity of science herself on the other, we have already met with an encouraging response. Our subscribers now number nearly five thousand; that is, we have, on a moderate estimate, fifteen thousand readers. . . .

"We state this, not only because the statement is almost due to our contributors as a justification of our demands on their time, but because it indicates the work—we almost said the noble work—which lies before them. Surely at a time when England would gain so much by the scientific education, not only of her Workmen but of her Ministers, an attempt to place Science before the Public, week by week, as Politics, Art, Music, and a hundred other things are placed before them, must not be suffered to flag; when the number of science-teachers and science-students is daily increasing, and the necessity for combined action and representation among scientific men themselves is being more and more felt, the popularization of science becomes more important than ever."

Why is the Sky Blue?

"H. A. N." has a letter under this title. He remarks: "Is it that the predominant colour of sunlight being orange, the regions devoid of sunlight appear of the complementary colour? . . . Or, again, is the blueness merely the colour of our atmosphere, as Prof. Tyndall's experiments have led some to believe? In favour of the former explanation, is the fact that the maximum intensity of the light of the solar spectrum is in the orange, and indeed that the sun *looks* orange, and if we close our eyes after gazing a moment at him when high up in the sky, we see a blue image. When the sun is low, his colour changes from orange to red, and this would explain the green tints so often seen in the cloudless parts of the sky at sunset."

At a meeting of the German Chemical Society on March 28, Prof. Rammelsberg read a paper on the phosphates of thallium, in which he stated that isomorphism exists between certain hydrogen thallium and hydrogen ammonium phosphates. He claims this is the first proof of the isomorphism of hydrogen with monatomic metals.

Mr. (afterwards Sir) E. B. Tylor read a paper "On the Philosophy of Religion among the Lower Races of Mankind" before the Ethnological Society on April 26. He said that the conception of the soul as recognized by the lower races is the starting point of their religious philosophy, which he described as 'animism'.

A Natural History Society has been established at Winchester College.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Tuesday, May 7

Zoological Society of London, at 5 p.m.—Dr. E. L. Taylor: "On Pseudo-rumination in the Rabbit". Dr. J. S. Huxley, F.R.S., and J. Fisher: "Hostility Reactions in Black-headed Gulls".

Royal Institution, at 5.15 p.m.—Sir John Orr, F.R.S.: "National Food Requirements".*

Wednesday, May 8

Institute of Metals (at the Institution of Mechanical Engineers).

At 2 p.m.—Dr. L. Northcott: "The Influence of Alloying Elements on the Crystallization of Copper, Part 2, Large Additions and the part played by the Constitution"; Dr. Maurice Cook and Dr. T. Ll. Richards: "The Structural Changes in Copper affected by Cold Rolling and Annealing"; Dr. Marie L. V. Gayler and R. Parkhouse: "The Ageing of High-Purity 4 per cent Copper-Aluminium Alloy".

At 7 p.m.—Prof. J. D. Cockcroft, F.R.S.: "The Cyclotron and its Applications" (Thirtieth Annual May Lecture).

Thursday, May 9

Royal College of Surgeons of England, at 4 p.m.—Prof. E. D. Adrian, F.R.S.: "The Nervous Mechanism of Pain."

Institution of Electrical Engineers, at 6 p.m.—Annual General Meeting.

Association of Teachers in Technical Institutions (Thirty-first Annual Conference, at the Hotel Russell, Russell Square, London), May 11–12.

May 12, at 10 a.m.—S. H. Moorfield: Presidential Address.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Lecturer in Electrical Engineering subjects at the Cardiff Technical College—The Director of Education, City Hall, Cardiff (May 9).

Lecturer in Engineering—The Principal, County Technical College, Stoke Park, Guildford (May 11).

Temporary Civil Engineering Assistants in the Borough Engineer's Department—The Borough Engineer, Town Hall, West Ham, E.15 (May 11).

Assistant Superintendent, Mathematical Instrument Office of the Survey of India, Calcutta—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting Appointment 290/10) (May 14).

Head of the Department of Chemistry—The Secretary, School of Metalliferous Mining, Camborne, Cornwall (May 15).

Construction Engineer for the Irrigation Department of the Government of Ceylon—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9322) (May 17).

A Senior Lecturer in Civil Engineering, a Lecturer in Civil and Mechanical Engineering, and a Lecturer in Mechanical Engineering, at the Henry Lester Institute of Technical Education, Shanghai—Viney, Price and Goodyear, Empire House, St. Martin's-le-Grand, E.C.1 (May 18).

Principal of the Wellingborough Technical Institute—The Secretary for Education, County Education Offices, Northampton (May 20).

Assistant Engineer for the Malayan Public Works Service—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9306).

Assistant Engineer to the River Avon (Bristol) Catchment Board—The Clerk and Solicitor to the River Avon Catchment Board, 11 Marsh Street, Bristol 1 (quoting 'Assistant Engineer').

BOOKS IN WAR-TIME

WILL books be made subject to the Sales Tax proposed by the Chancellor of the Exchequer, and if so what may be the results ? So far as can be ascertained up to the present it is not proposed to allow any exceptions in the home market, outside the domain of food and drink, and the resultant anxiety of all who are familiar with book-trade economics would undoubtedly be shared by every thinking man if the very special facts of the case were generally understood. In the following very brief survey of a very complex problem, it has been impossible to attempt more than the sketchiest of outlines, but it may be hoped that it will do something to correct some common misapprehensions and perhaps enlist some sympathy for the claim of books to special consideration. This claim has been emphatically put forward by the National Book Council, in an urgent call for action recently circulated to every society and association of a cultural nature.

To the printed book we owe the preservation of the philosophy, the scientific knowledge, the religion and the poetry of the past. Upon the book depends the comparative examination of rival theories, the precise record of all experimental work. In short, civilization as we know it to-day is the child of the printed word, and upon the printed word, written under the twin inspirations of intellectual freedom and love of truth, depends all hope of further progress.

Out of the almost universal recognition of these truisms there has arisen a tradition, never yet over-ridden in Great Britain, that a tax upon books would constitute an unfortunate impediment to free speech and a tax upon literature and learning. It is therefore not surprising to find that the National Book Council is exerting itself actively to organize, before it is too late, effective opposition to the proposition now under review. The National Book Council was founded in 1927 to promote the use and appreciation of books of all kinds, from the novel to the technical treatise, and the membership is open to all who care for books.

The letter to which reference has already been made was sent at the instance of this body's Consultative Committee, through which is maintained liaison with many of the most important educational bodies, learned societies and social organizations in the country.

In this Committee's manifesto, it is claimed that the application of a sales tax to books would be "inimical to the best interests of research, study and recreation", and that "in addition it would tend to disrupt still further the whole educational programme of the nation—a programme already suffering from disorders caused by the war". Let us examine this claim.

The Chancellor of the Exchequer, in introducing the principle of the sales tax, made it clear that its purpose is at least as much to discourage internal expenditure as to raise funds towards the successful prosecution of the War, and from this it is fair to assume that in the eyes of the Government books are to be regarded simply as a commodity, just like any other, the consumption of which must be discouraged as cheerfully as, perhaps, the luxury cosmetic or the unnecessary spare suit. This attitude, which is discouraging to all who deplore the widespread tendency to regard books as luxuries, cannot be allowed to pass unchallenged, if the nation is not to find itself without books, publishers to produce them or booksellers to sell them. Fortunately there is hope of persuading the Government that books have, quite apart from their cultural influence, a very considerable economic value to the nation at war, besides being absolutely essential to the presentation of the British case to the eye of ally and neutral.

In this connexion we cannot do better than quote the following paragraph from a "Memorandum on the Export of Books" submitted to the Export Council by the Publishers' Association: "The 'cultural' value of books is unique. The word 'cultural' does not at all adequately express what we have in mind and has narrow academic associations which we would gladly avoid. Nor is 'propagandist' a better word. What the book trade does, in general and apart from the particular purposes of particular books, is to publicize British habits, ideas and ideals over the entire world. It is consequently a continuing proof of the reality of the Allied Cause. The variety, vigour and freedom of British civilization are demonstrated through the whole range of its literary output, from the ordinary novel to the most serious critical and scientific works: and this continuous process cannot be allowed to flag without endangering British influence and prestige everywhere."

It has been repeatedly stressed that, for economic reasons, whatever happens to our internal trade, neither the proposed sales tax nor any other war-time legislation should interfere with British export trade. But apparently it is not realized that books, unlike most commodities or manufactured products, cannot be divided up into two water-tight compartments—home and export. The largest part of a book's production cost is the cost of setting up the type, and as this remains the same whether it is to be printed by the hundred or the thousand, it is clear that the largest possible circulation must be aimed at if the price is to be kept at an economic level. Another large fixed expense is the cost of placing the type on the printing machine and of 'making ready' for printing, a skilled and laborious job which is carried out by highly paid craftsmen. By the influence of these two factors is to be explained a large part of the price differences between newly printed books at 7*s.* 6*d.* and more, cheap editions and reprints from standing type at 3*s.* 6*d.* to 1*s.* 6*d.*, and "Penguins" at 6*d.* each which, though completely reset, spread the cost over editions of thirty to fifty thousand.

This being so, it is clear that if attractive price-levels are to be maintained in the export markets, the maximum home demand must be encouraged. If the home demand is artificially cut down editions will shrink, and prices will rise so sharply as to destroy the potential demand abroad and make impossible the publication of many books of the first importance. There are unfortunately no reliable statistics in the book trade, but a recently circulated *questionnaire* has shown not only that at least one third of the total book production of Great Britain is sold abroad, but that, in addition, valuable invisible exports are created by the sale of American film rights. If we add to this consideration the claim that the export of British books does much to unite the Empire, to demonstrate the British outlook and ideals all over the world and, incidentally, to prepare the way for the exporters of other British goods, we may reasonably conclude that its importance to the nation is out of all proportion to its monetary value.

It will be generally agreed that on cultural grounds alone, book prices should be maintained within a reasonable distance of pre-War levels. Unfortunately this aim becomes increasingly difficult of achievement, and it seems likely that the strenuous efforts to stabilize prices, which maintained them at pre-War level for the first three months of the War, will be utterly defeated by the situation in Scandinavia. An important factor in price fixing is the cost of paper, and the cheaper the book the more relatively important does this factor become. At the onset of the War, the Government took over the control of all paper supplies. A controller was appointed and a schedule of maximum prices was worked out, promptly imposed, and linked to a drastic rationing scheme which reduced the nation's consumption to 60 per cent of pre-War requirements. This restriction, combined with a heavy percentage increase in the price of paper, had already forced up the price of the standard cheap editions and of many, but not all, of the new spring books, when the Germans invaded Norway and attained the control of the Skagerrak by the occupation of Denmark.

The larger part of the wood pulp supplies which form the basis for most of our paper was cut off at a stroke and no one knows when, or if, it will be available again. The result was immediate and startling. A further increase in prices coincided with a 50 per cent cut in permitted consumption, and this was followed by an announcement that after the current licensing period a further severe cut in consumption, possibly up to another 50 per cent, will be necessary. At the time of writing, therefore, the book trade is wondering what it can usefully do with 15 per cent of its pre-War paper consumption, at prices more than 60 per cent above pre-War levels.

With wages, rates and fuel costs rising in competition, with compulsory war risks insurance to pay, and with the problems of evacuation to contend with, the situation was already critical for bookseller and publisher alike. Increased production costs call for 'longer runs', but such a scarcity of material will not only make this impossible but also will necessitate, on the contrary, much smaller editions than usual. It is difficult therefore to see how publishers will be able to avoid for much longer a dangerous increase in price-levels at a time when Government policy is to prevent general inflation and, by taxation, both direct and indirect, to limit internal expenditure. Already, we believe, the sale of new fiction and general literature has dwindled to a fraction of its pre-War volume, but the demand for books on the War and international politics, official Blue Books, memoranda and handbooks, together with standard cheap editions of the classics, old favourites and popular reference books, has gone far to cancel out the drastic effect of the evacuation in London and other evacuation areas, while elsewhere business has been quite brisk. But the War has scarcely begun, paper shortage has only just begun to take effect, and the real price increases are not yet upon us, though close at hand. The outlook of the immediate future, so far as book production is concerned, is gloomy in the extreme.

To this situation is now added the threat of a sales tax which may be anything from 5 to 25 per cent on to prices which by then will already have risen. Such an impost would be a veritable tax on literature and culture. Books are often the first objects of personal economy, and this can unfortunately also be said with equal truth of the councils and committees of local government and public education. Even in peace-time conditions expenditure per head on books in Great Britain is very much below that which is accepted as normal to the Finns, the Germans the Scandinavians or the French. As has been said, no statistics exist, but it has been possible to make approximate estimates within a generous margin of error, and as a typical illustration it may be of interest to recall that according to the estimate of the Consultative Committee on Books in Public and Elementary Schools which reported to the Board of Education in 1928, the average annual expenditure on books, per head, was certainly not in excess of 1*s.* 8*d.*, and it has not shown much sign of improvement since that date.

Were there greater mental alertness and intellectual curiosity, books would be able to perform adequately the service which they now offer too often in vain, and their producers would be able to supply, at prices within the range of every pocket, new works of literature, of learning and of reference which at present are confined to the shelves of the libraries and the dwindling regiment of the bibliophiles. It is to extend and develop this wider interest in, and appreciation of, books that the National Book Council was formed.

The production of books is authoritatively stated to consume only 2 per cent of the nation's normal paper supplies, and a reversion to the earlier allowance of 60 per cent of normal, which would enable the publishers to carry on with reasonable efficiency, would therefore call for the re-allocation of about 1 per cent of the nation's pre-War supplies. In practice, by careful selection and economy in production, it would probably be possible for the book trade to carry out its important functions on an even lower allowance; but precisely how much this would be is probably best left to the Publishers' Association.

The present international crisis threatens to bear with undue weight on book production. Learned and educational organizations may be expected to give active support to the appeal for special consideration for books. If disaster to the intellectual life and the intelligent recreation of the nation is to be avoided, books should be exempted from the sales tax and accorded a wholly disproportionate share of the available supplies of their raw material—paper.

Long-range planning is a necessity in book-production as in many other fields, and without an early pronouncement on the position, an important part of the nation's effort is being held up. The case appears to be so strong that the urgent representations now being made can, one may hope, scarcely fail to have their effect. But the desired result will be more quickly and more completely attained if all those who realize the place of books in the social, intellectual and economic fabric of the nation use their influence wherever it may be most effectively applied.

DESCRIPTIVE AND PREDICTIVE SCIENCE

Science To-day and To-morrow
By Waldemar Kaempffert. Pp. 262. (London: Ivor Nicholson and Watson, Ltd., 1940.) 10*s*. 6*d*. net.

MUCH more is done in the United States than in Great Britain to interest the general public in scientific progress. Nearly twenty years ago, the late Mr. E. W. Scripps, a newspaper proprietor and editor, provided a sum of more than 100,000 dollars to establish the organization called Science Service, with a staff of competent writers who simplify and illuminate scientific news for the public Press; and newspapers in all parts of the country are subscribers to this service. Many of the leading newspapers have, in addition, permanent members of their editorial staffs to describe and comment upon scientific matters. Dr. Kaempffert, the author of this book, occupies an honoured position of this kind, as science editor of the *New York Times*; and his contributions are widely read and appreciated. Some of the material in the book appeared originally in that newspaper and other magazines; and all of it represents the reactions of an informed and thoughtful mind to the results of scientific investigations in the realm of natural knowledge.

Each of the eighteen chapters can be read and understood independently of what precedes or follows it, though the general arrangement seems to represent successive aspects of the heavens, terrestrial forms of matter, life, man and the machine. Under the title, "A Star Explodes", the first chapter deals with modern observations of new stars and presents views held by leading authorities as to their origin and nature. There are reasons for believing that, in the course of their existence, most stars are likely to have immense stores of energy suddenly released by the near approach of another body or by conditions of internal instability. The planets of the solar system were formed from streamers drawn out of the sun by the gravitational influence of a passing mass; and a similar explosion may be caused in the distant to-morrow by another approach or by changes of atomic structure. Either of these events would mean the end of the earth and the possible beginning of a new world—organic as well as inorganic. The end of the sun as we know it is inevitable, whether by celestial accident or by loss of radiation through atomic changes discussed in the succeeding chapter; and "man will be blotted out by forces that were hostile to him from the beginning of time and over which he triumphed for a brief hour".

The next chapter, entitled "Birth and Death of the Moon", is a short outline of the theory of tidal evolution applied to our satellite, ending in its near approach to the earth, the consequences of which are catastrophic changes in the crust, while great fragments of lunar mountains fall upon the surface or revolve around the earth as a ring of meteorites which are met so frequently that our globe becomes a blackened and dead world drifting through space. The curtain falls on the death of mankind as the result of all these celestial events; and, after bringing together in another chapter what has been revealed in recent years as to the atmospheres and constitutions of the planets, "it seems as if only the earth is capable of supporting the highest forms of life—for the one freakish world in a freakish solar system." Copernicus deposed the earth from its place in the centre of the universe which the presumption of man had given it; astronomy now suggests that both it and mankind are consequences of a series of accidental circumstances.

It must not be supposed, however, that Dr. Kaempffert, like Joe, the fat boy in "Pickwick Papers", "wants to make your flesh creep" by confining himself to forecasts of man's terrestrial destiny suggested by modern astronomical knowledge. Man has already devised artificial means of maintaining human life under unnatural conditions. In his hermetically sealed gondola, Piccard lived for a few hours and made new observations of the earth's atmosphere at altitudes never before attained by a human being; and by his ascent he became the first of a new type of explorers. Science of to-morrow may enable the journeys to be extended until it becomes possible for man to be shot off or rocketted through space to such a planet as Venus, which by that time may be adaptable to human habitation. Meanwhile, science to-day is accumulating much new knowledge of the nature and conditions of the upper air and beyond, and Dr. Kaempffert traces these developments from the explorations of Teisserenc de Bort to the present time.

It is through such investigations that we may hope to obtain further information as to the origin of cosmic rays and their relation to atomic processes. A good chapter is devoted to modern work on the physics of the atom; and we read, "Out of atom-bombarding, out of the intellectual effort to explain what the atom is, comes a new, profound, and stirring conception of the universe and our place in it".

Such are the subjects and general outlook of the first seven chapters of the book. The position and prospects of the subjects of the remaining eleven chapters are similarly treated. It is sufficient here to say that these chapters are concerned with the passing of the Coal Age and the possible uses of other sources of energy; achievements of synthetic chemistry; the creation of living organisms; cell structure in relation to processes of organic evolution; Alexis Carrel's work on tissue culture and the uses of Lindbergh's perfusion pump; transient man and his reactions; lightning and other high-tension discharges; mechanical aspects of the attainment of speed (H. E. Wimperis's British Association address on "The Future of Flying", at Dundee last August, could have provided some striking points for this chapter); internal mechanism of the *Queen Mary*; the calling up of personalities of the past or present through radio and television and the preservation of sense impressions; and the relationships of science to social evolution.

Dr. Kaempffert's main aim has been to present important aspects of scientific work and thought to an intelligent public; and to suggest some of their social consequences or implications. In his forecasts of events or possibilities which will influence the future of the earth and mankind, he rarely goes beyond what some scientific men themselves have fancied may happen; and he cannot, therefore, be accused of ministering to scientific sensationalism. Almost every one of his chapters provides the basic material for an imaginative scientific fantasy or romance; and Mr. H. G. Wells, the master of such literature, has already exercised his genius in the production of many absorbing stories of this type. Dr. Kaempffert may be said to occupy a place between the purely descriptive writer, who is making scientific knowledge interesting and intelligible to general readers, and the man of letters, who occasionally lets his mind play upon the potentialities of discoveries made in scientific fields. His work is an excellent example of what can be done to educate the public in the spirit of science and the human meaning of the results achieved.

R. A. GREGORY.

THE LOUSE AND LOUSE-BORN DISEASES

The Louse
An Account of the Lice which Infest Man, their Medical Importance and Control. By Prof. Patrick A. Buxton. Pp. ix+115. (London: Edward Arnold and Co., 1939.) 7*s*. 6*d*. net.

THE louse of man, *Pediculus humanus*, is concerned with the transmission of the micro-organisms of at least three of his diseases. From the medical point of view, therefore, it is a creature of importance and especially during periods of war. The most virulent of these diseases is epidemic typhus which, in Europe, occurs in the U.S.S.R., the Balkans and many parts of the Mediterranean region. In recent years it has steadily receded and disappeared not only from England and Wales but also from western Europe. It is noteworthy that it did not break out on the Western Front during 1914–18, notwithstanding the virulent epidemics that prevailed in Serbia during that period. The second louse-borne disease is trench fever which, it will be recollected, was so prevalent in the armies of the Great War. Yet, when that calamity ended, the disease vanished from western Europe while the louse still remains. Relapsing fever is the third louse-borne malady and is widely distributed in eastern Europe, where epidemics prevailed during the years 1914–18.

In the present crisis the louse problem is likely to force itself once more into prominence. We need to go beyond existing empirical methods of delousing: to deter infestation is a possibility of prime significance. The disappearance of trench fever at the end of the War of 1914–18 stopped further inquiry. Whether infection is solely by means of the entry of the virus, in the dried fæces of the louse, through scratches or abrasions, or perhaps via the conjunctiva and respiratory tracts also, needs renewed inquiry. The curious feature seems to be that Pediculus does not generally convey any of the three diseases named by means of its blood-sucking mouthparts. It is evident that while knowledge of the louse and its economy has greatly increased during and since the War of 1914–18, certain essential information still remains a desideratum.

Dr. P. A. Buxton in his handbook has given an accurate and concise summary of our present knowledge of both Pediculus and Phthirus together with methods for their control. Originally written as part of a larger work on medical entomology, which is in preparation, the importance of the subject in civil and military life at the present time led the author to publish this section in advance. The army medical officer, in particular, should have this convenient little manual available, since it provides a clear exposition of aspects of the subject likely to be overlooked and indicates where further inquiry is needed.

A. D. IMMS.

ECONOMIC WARFARE

(1) Economic Warfare
By Paul Einzig. Pp. x+151. (London: Macmillan and Co., Ltd., 1940.) 7*s*. 6*d*. net.

(2) The Economic Effort of War
By R. W. B. Clarke. Pp. 252. (London: George Allen and Unwin, Ltd., 1940.) 7*s*. 6*d*. net.

THE volume of informed criticism of the Government's economic policy and the continued pressure for the inclusion in the Cabinet of a Minister for Economic Affairs, which were in no way dispelled by the speeches of the Prime Minister or the Chancellor of the Exchequer in the recent debate on economic organization in the House of Commons, indicate that there is a far more widespread appreciation of the importance of economic questions at the outset of the present War than at almost any time during the struggle of 1914–18. This difference is brought out strikingly in the early chapters of Dr. Einzig's book, and the existence of such interest and informed opinion make the more regrettable the failure of the Government to take the public into its confidence, to explain what is happening and to enlist its co-operation.

To some extent, what the Government failed to do is being done by an admirable series of pamphlets and books on economic questions of the War. The Oxford series of pamphlets on world affairs have included lucid expositions by Geoffrey Crowther of the economic and financial aspects of our war effort. The same aspects have also been discussed in a number of broadsheets issued by Political and Economic Planning (P E P), and Dr. Einzig's volume is a more detailed but no less lucid exposition of these matters, more particularly with reference to the use of economic policy and methods in pursuance of our war objective. If the reader couples with this volume, for example, a study of Mr. R. W. B. Clarke's "The Economic Effort of War", he could scarcely be better equipped to appreciate the significance of the economic factor or exactly what is required of him in the way of intelligent co-operation as a citizen. The Government should be grateful for the invaluable contribution which both these books make towards the education of public opinion and the preparation of the citizen alike for the contribution and the sacrifices which the prosecution of our war effort inevitably entails.

(1) Dr. Einzig does not exaggerate the importance of the economic factor and of economic warfare. While economic factors are likely to play a very important part in determining the outcome of this War, they can only produce their full effect in conjunction with military, naval and air force operations, and in his realistic analysis of the situation he emphasizes the necessity to prepare for a prolonged struggle. In regard to productive capacity, he stresses the importance from the outset of taking steps to increase the production of those goods which are required directly or indirectly for national defence purposes or are essential for the maintenance of the civil population, as well as to reduce or stop the production of non-essential or luxury goods, even if they only interfere with the increase of production of essential materials. Stress is also laid on the collection of statistical material as a basis for reorganization to enable national production to replace imports as far as possible.

The Government is criticized by Dr. Einzig for not taking adequate measures in some such fields, notably in regard to agriculture, prior to the outbreak of the War, but pays tribute to the rapidity with which emergency legislation was adopted within a few weeks of the outbreak of the War. After examining problems of production, distribution and consumption, foreign trade, public finance and foreign exchange he proceeds to discuss the methods of economic warfare and the war economy of Germany, France, Japan, the Soviet Union and the United States, as well as of Italy, before reaching his emphatic but reasoned conclusions that the superiority of the economic resources at the disposal of the Allies compared with those of Germany will in the long run be of decisive importance.

Dr. Einzig is under no illusion as to the intensity of the effort or sacrifices involved. He advocates ruthless rationalization, for example, and strong measures against luxury consumption, and he is prepared to support both industrial conscription and the conscription of labour. In this he differs from Mr. Clarke, who considers that from the military point of view, or that of public morale or increasing output and efficiency, it would be a mistake to try to impose industrial conscription at the present time. Mr. Clarke stresses the important contribution which the trade unions have to make to the national effort, and the necessity of enlisting that co-operation freely.

Dr. Einzig is, indeed, on the whole less critical of the Government effort than Mr. Clarke, though no less bold in his outlook or suggestions. His criticism is indirect or implied rather than direct, whereas Mr. Clarke's two chapters on Government control and the first six weeks of the War are among the most valuable in his book and should be of special interest to scientific workers. Their constructive criticism affords one of the best presentations of the argument for Cabinet reconstruction and the necessity of a Ministry of Economic Planning with its appropriate General Staff that has yet appeared.

Both these books should, in fact, be widely and appreciatively read, and should, as already indicated, assist in that educational work indispensable in our war effort, which the Government itself has largely neglected. It may well be hoped that their constructive criticism and suggestions—Dr. Einzig makes a shrewd comment and suggestion regarding economic propaganda and its use to undermine German economic morale which it is to be hoped will not fall on deaf ears—will be duly weighed by the Government as well as the general public. At least it is certain that these excellent contributions to the growing mass of useful literature on the economic side of the War will contribute to the rapid formation of a public opinion which will render it impossible for the Government to continue its hand-to-mouth policy and attitude of drift in economic matters. They should force upon it the coherent policy, planning and organization which form the indispensable basis for that drastic limitation of non-essentials, comprehensive mobilization of industrial resources and vigorous prosecution of every aspect of economic warfare which are essential to the success of our war effort.

R. Brightman.

THE INDIAN FRAGMENT OF GONDWANALAND

Regionale Geologie der Erde
Herausgegeben von Karl Andrée, H. A. Brouwer und W. H. Bucher. Band 1, Abschnitt 6: The Indian Peninsula and Ceylon, by G. de P. Cotter. Pp. 66+vi. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1938.)

Dr. G. de P. Cotter, until recently a superintendent of the Geological Survey of India, has utilized the experience of a lifetime spent in the field in India in summarizing the present state of knowledge of the geology of the peninsula. There are no Palæozoic rocks there older than the Talchir Boulder Bed at the base of the Gondwanas, which is regarded, with fair confidence, as Upper Carboniferous. The glaciation was more intense in the south, where ice-scratched rockfloors and boulders occur, whereas in the Himalayas (in Spiti and Kashmir) the representative of the Boulder Bed is a basal conglomerate which may have been deposited by floating bergs. Since India is the only land north of the equator where the Boulder Bed occurs, Cotter is inclined to accept the hypothesis of continental drift and to regard the Indian fragment of Gondwanaland as having drifted northwards from its original home south of the equator, leaving behind it portions of its mass in Madagascar, the Chagos archipelago and the submerged land which forms the platform of the Maldives and Laccadives. Elsewhere the latter is regarded as the extension of the Aravalli Range.

The impact of this great land mass with the "northern continent" occurred, according to Cotter, in the close of the Cretaceous, and is associated with the outpouring of the Deccan Lavas now assigned definitely to the Danian. Incidentally, the evidence is steadily growing that the folding of the Indo-Malayan mountains and the intrusion of the tin-bearing granites of Burma and Malaya are of the same age. Further drifting of the land mass helped in Tertiary times to build the Himalayas and to elevate Eocene marine rocks to heights of more than 20,000 feet.

Cotter accepts the work of Spath on the cephalopods from Upper Gondwana beds of the Madras coast. These beds, once claimed by Waagen as Neocomian but long since regarded on the evidence of plant remains as Middle Jurassic, are now classed as Upper Neocomian, possibly Aptian, so that the Upper Gondwanas range in age from Upper Trias to Aptian, most of Jurassic time being represented by a stratigraphical break.

Most of the book is naturally devoted to the Pre-Cambrian—falling into the two great groups, the Purana or Algonkian and the Archæan. The Purana as a whole are unaltered sediments and in the Peninsula generally horizontal or only slightly disturbed, but in the Aravalli Range there was marked folding in Middle Purana times. The threefold division of the Puranas is into Lower (Cuddapahis and Delhis), Middle (Lower Vindhyans) and Upper (Upper Vindhyans and Karnuls). Cotter admits the many problems still unsolved in the geology of the Archæans but regards as definite that the Bundelkhand gneisses, Singhbuhm metamorphics and Berach granites (Group I) are the oldest rocks of the country; that the Closepet Granite, Charnockites (Group V) and Peninsular or Foliated Gneisses (Group IV) are newer than the metamorphosed sediments (including the Dharwars and Aravallis, Groups II and III) with which they are associated.

L. Dudley Stamp.

THE DEPARTMENT OF SCIENTIFIC AND INDUSTRIAL RESEARCH

TWENTY-FIFTH ANNIVERSARY

WHEN Mr. J. A. Pease, the then president of the Board of Education, in introducing the Board of Education estimates in the House of Commons on May 13, 1915, announced the impending appointment of an Advisory Council for industrial research in Great Britain, to be specially entrusted with the supervision and encouragement of scientific research particularly in relation to industry, he laid special stress on the importance of providing for the training of the scientific and technical personnel. Already the early months of the War of 1914–18 had revealed the dangers and difficulties in which Great Britain was placed through the neglect of science by industry and the absence of an adequate scientific personnel. We had not merely to make the best use of the scientific men we then possessed, but also to provide a further supply in the future. The debates in the House of Commons on the proposals eventually issued by Mr. Pease's successor at the Board of Education, Mr. Arthur Henderson, in a White Paper (Cmd. 8005), as in the original statement, thoroughly endorsed the Government's proposal to deal with this problem as an integral part of a comprehensive improvement in our educational system. It was indeed originally proposed that the whole scheme should be supervised by the Board of Education, to which the expenditure of £1,000,000 over a period of five years would be entrusted on the advice of the proposed Central Council of Commercial and Industrial Research.

The reports of these debates reveal after twenty-five years the immense debt of the nation to those whose vision and courage launched this venture even in the days of war. That the outbreak of war in September of last year found Great Britain with resources in scientific and technical personnel adequate to meet all demands is due in no small measure to the foresight and energy of such men as Lord Haldane, Lord Balfour and Dr. Addison, and the wise guidance of such successive chairmen of the Advisory Council as Sir William McCormick and Lord Rutherford. Whatever concern may have been expressed as to the use which is being made of available scientific personnel or resources, except perhaps in a few fields such as those of the social sciences, the ability of the scientific workers and the research organization of the country to meet whatever demands may be made upon them by the War is beyond question. Even before the War of 1914–18, scientific workers in Great Britain, if few in number compared with those of some other countries, had many outstanding achievements to their credit and were playing their full part in scientific advance. For the great advance in the numbers of British workers, and unprecedented expansion in the application of scientific research in industry and in every phase of national life in the last quarter of a century, without any impairment of that capacity, no small share of the credit must be given to the Advisory Council of Scientific and Industrial Research, first established by Order in Council on July 28, 1915.

The White Paper which outlined the scheme alluded to the difficulties in which many of our industries had been placed in 1914–15 through our inability to produce at home certain articles and materials required in trade processes, the manufacture of which had become localized abroad, because science had there been applied more thoroughly and effectively to the solution of scientific problems bearing on trade and industry and to the elaboration of economical and improved processes of manufacture. To advance or even maintain our industrial position it was essential to aim at such a development of scientific and industrial research as would place us in a position to expand and strengthen our industries and to compete successfully with the most highly organized of our rivals. The scheme was designed to establish a permanent Department for the promotion of industrial and scientific research.

For this purpose a Committee of the Privy Council was set up, responsible for the expenditure of any new moneys provided by Parliament for scientific and industrial research, and an Advisory Council, responsible to the Committee of Council, and composed mainly of eminent scientific men engaged in industries dependent on scientific research. The prime functions of the Advisory Council were and are to advise the Committee of Council on proposals for instituting specific researches, or for establishing or developing special institutions or departments of existing institutions, for the scientific study of problems affecting particular industries and trades, and on the establishment or award of research scholarships or fellowships. The Advisory Council is also available to advise the education departments as to the steps which should be taken for increasing the supply of workers competent to undertake scientific research.

The Advisory Council, which met for the first time on August 17, 1915, was further directed to frame a programme for its own guidance in recommending proposals for research and for the guidance for the Committee in Council in allocating such State funds as might be available, designed in advance to operate over some years, having regard to the relative urgency of the problems requiring solution, the supply of trained investigators available, and facilities in laboratories or equipment which could be provided. The method of approach adopted by the Council is indicated in its first report. The Council was under no misapprehension as to the relation between pure and applied science. It was decided to give science in its application to industry precedence over pure science in the Council's deliberations, and after a period of careful inquiry and consultation to initiate a gradual and systematic attack upon a wide and carefully selected front.

The soundness of the policy and principles outlined in the first report of the Advisory Council is attested by the results which have followed from these modest beginnings. Realizing from the start the dependence of the success of its work upon a greatly increased supply of research workers and upon a hearty spirit of co-operation among all concerned, whether scientific workers, business men, professional and scientific societies, universities and technical colleges, local authorities and Government departments, it was recognized also that neither condition would be effective alone. The first condition of success was at the start unattainable, and even at the end of the War of 1914–18 the number of trained research workers was insufficient for the demand. Effective research, particularly in its industrial application, calls increasingly for the support and impetus that come from the systematic team-work of investigators of mediocre ability, working intelligently under the direction of first-class leaders.

The problem of the supply of investigators of the requisite abilities in sufficient number is largely a matter for the education departments. It is not entirely a matter of the provision of scholarships, but depends also on the standard of students entering the universities. None the less, in the first ten years, as the report of the Advisory Council for the year 1925–26 shows, much was done to re-establish a body of scientific workers of the highest rank for purely scientific work, and to enable men who intended to make some branch of industry their profession to equip themselves for scientific work in industry by postgraduate research work.

Of the seven hundred allowances given in the first seven years, nearly four hundred were to students of chemistry, and in its report the Advisory Council expressed the opinion that too many men were encouraged to specialize in chemistry. The records of the Department showed that large numbers of applications were received whenever a post for chemical research was advertised, while the demand for men who combined a study of chemistry with other subjects such as agriculture, biochemistry or botany outstripped the supply. There was also a scarcity of men interested in, and capable of, the application of general physics in industry, a position which has hardly been improved in the subsequent fifteen years, as the experience of the Central Register indicates. Although the proportion of grants held by students in training in biology has steadily increased in recent years, and has for some years been equal to or greater than those held by students in physics, students of chemistry have consistently been at least twice as numerous as those of students in any other branch of science in receipt of grants.

The service which the Department of Scientific and Industrial Research has rendered to the development of pure science is far from being limited to the provision of maintenance allowances for students or even special assistance to independent research workers, whether by helping young research workers of exceptional ability to pursue their work for a limited period without the necessity of finding other employment, by the provision of funds for research or technical assistants or the purchase of special apparatus and equipment, or, in special circumstances, by making really substantial grants. The Advisory Council has consistently shown in its reports a wise concern for the conditions of employment of the research worker, whether in regard to salary or security of tenure ; this is a contribution to the raising of standards in the last two decades which has earned the cordial appreciation of all scientific workers.

In regard to the actual prosecution of research, the record of the twenty-five years work of the Department makes impressive reading. It includes the development and expansion of such institutions as the National Physical Laboratory and the Geological Survey and Museum of Practical Geology, which were already in existence and were taken over by the Department. It includes the establishment of the Fuel Research Station at Greenwich, the Building Research Station at Watford, the laboratories of the Food Investigation Board at Cambridge, East Malling, Chipping Campden and Torry, the Forest Products Research Laboratory at Princes Risborough, the Radio Research Station at Slough, the Chemical Research Laboratory at Teddington, and the Road Research Station at Harmondsworth.

At these stations and under the direction of the various boards or committees of the Department, research has been initiated on a national scale into such fields as fuels, forest products, food, water pollution, transport problems. Simultaneously, through the co-ordinating boards set up in 1920, the research departments of the Fighting Services have not only been placed on a secure footing but also brought into effective contact with the work of the Department. Medical research and agricultural research have also expanded considerably in the period, often in co-operation with the work of the Department, while in 1925 there was formed the Committee of Civil Research to advise on broad questions of national policy involving scientific and industrial research on much the same lines as the Committee of Imperial Defence.

Besides all this co-ordination of existing organizations and initiation of fresh lines of work, the Department has done much to stimulate research on questions of interest to the Dominions and Colonies, and to secure co-ordination with the corresponding departments formed overseas, such as the Council for Scientific and Industrial Research of the Commonwealth of Australia, the Department of Scientific and Industrial Research of New Zealand, or the National Research Council of Canada, notably in investigations on food problems or such matters as Empire timber. In such imperial problems and in the more domestic problems of Great Britain, the Department has succeeded in promoting co-operation between the different interests concerned, whether consumers, manufacturers, Government departments or others in the attack on common problems.

To the extent of that co-operation the development of the research association movement in Great Britain bears emphatic witness. On December 1, 1916, in receiving a deputation of the Board of Scientific Societies, Lord Crewe, as Lord President of the Council, announced the intention of the Government to ask Parliament to place a million pounds at the disposal of the Department to enable it to co-operate with the industries of the country in the foundation and maintenance of approved associations for research during the following five years or more. This fund was duly voted by Parliament and became available in July 1917; the scheme had been outlined in detail in a paper issued by the Department in June 1917. The scheme visualized the systematic development of research and the co-operation of science with industry carried out under the direct control of the industries themselves. In this way it was hoped to avoid the danger that, if the work were done by the State or the universities, the results would not be put into immediate operation, and as they would necessarily be published, might become of equal or greater benefit to foreign competitors. Moreover, it was hoped that co-operation of the firms engaged in any one industry might enable research work to be undertaken which could not have been dealt with by a single firm.

The rapid progress made under the scheme was indicated in the excellent account issued in 1927 under the title "Co-operative Industrial Research", and when on the exhaustion of the Million Fund the Advisory Council devoted the greater part of its annual report for the year 1932–33 to a review of the scheme, it was able to point to important practical achievements as well as to evidence that the scheme had contributed to a definite acceleration in the advance of industrial science. The first four associations were licensed by the Board of Trade under the scheme in 1918, followed by ten more in 1917, nine in 1920 and one each in 1921, 1923, 1930, 1937 and 1938; two more were formed in 1926, as well as similar organizations in 1929 and 1931, though not of the same formal and legal status, by the National Federation of Iron and Steel Manufacturers and the Institution of Automobile Engineers.

Certain of the associations never became effective, and some after several years active work ceased to operate or became merged in other bodies fulfilling similar functions. The last report of the Department shows, however, that there are still twenty-two research associations in existence, serving a very wide range of industries, and achievements to their credit already offset very largely the expenses of their work. For example, it has been computed that, in the first ten years of its work, the researches of the Electrical Research Association on insulating oils, costing £8,500, had involved savings to the industry of at least £100,000 a year. Further researches on buried cables, costing £18,000, had represented a saving to the industry of at least £250,000 per annum and added four millions to the value of the existing cables. Investigations of the British Cast Iron Research Association, if fully adopted, would result in the saving of fuel and other economies of £200,000 per annum. Almost equally striking savings have resulted from investigations conducted by the Non-Ferrous Metals Research Association on ternary lead alloys used in sheathing cables and for water-pipe service, and by the Refractories Research Association on prolonging the life of saggars.

The significance of such achievements in the present urgent need for national economy in every sphere is obvious, but too much stress should not be laid on such concrete examples. Often it is difficult to assess at all accurately either the direct or the indirect results of such research in stimulating a scientific approach to industrial problems and the application of scientific knowledge in industry. The Advisory Council has from the start been alive to the importance of securing not merely the initiation of industrial or scientific research but also the utilization of its results by industry. "One of our most important tasks", wrote Lord Rutherford in the 1935–36 report, "is so to organize the conduct of research as to promote contact with industry", and this is one of the main reasons for attaching so much importance to the development of the research association movement. The application and development of scientific ideas in industry depend upon a complete understanding of the way in which industry can make use of science and scientific method.

So far back as its 1930–31 report, the Advisory Council noted the extent to which the time of the staff of a research association was occupied in work for the firms which constitute it and in visits to works, thus functioning as the 'general staff' of the industry ; further, increasing attention has been given to the presentation of the industrial and financial implications of scientific data in publications so as to facilitate their utilization on a wide scale in industry.

However admirable the results achieved by many of the research associations, the movement has been open to criticism on account of the inadequate scale on which it has been financed. Moreover, the success which has attended the scheme of block grants which was initiated as a result of a review of the situation during 1933–34 and later discussions with the various associations should not lead us to overlook the fact that, although the total sum subscribed by industry has increased by forty per cent to more than a quarter of a million pounds per annum since the scheme came into operation, there are still associations receiving insufficient financial support from the industry to qualify for the block grant.

Important as the research association movement may be, it provides only one example of the way in which the work of the Department has led to increasing value being placed upon research by the leaders of industry. An admirable example of the way in which progress has been made in gaining the confidence of industry is provided by the work of the Water Pollution Research Board, the youngest of the major research activities of the Department, notably in relation to the disposal first of polluting waste waters from the beet sugar industry and later in the treatment and disposal of effluent from dairies and the manufacture of milk products. The developments referred to in the last report of the Advisory Council in relation to the testing of electrical switchgear by the National Physical Laboratory provide a further example of this tendency, while equally striking illustrations might be found in such fields as the testing or specification of building elements for their resistance to fire, or the work of the Building Research Station or Steel Structures Research Committee in co-operation with various branches of industry. The importance of the work of the Building Research Board of the Department in securing the most economical use of all building materials in war-time need scarcely be further stressed, whether in view of the magnitude of the Government's building programme alone, which for 1940 is estimated to cost about £200,000,000, chiefly for aerodromes, storage depots, and factories, or with regard to the necessity for conserving to the utmost our resources of steel and timber and reducing imports. Dr. E. V. Appleton, the present secretary to the Department, recently indicated that adoption of the Board's recommendations would permit substantial economies in timber and steel, and special arrangements have been made by the Government for dealing with the technical problems of building created by the War.

The research work which the Department itself has developed in the national interest has in general been that required to deal with such primary needs of man as his food, fuel, building, the use of timber and the protection of his drinking water or the atmosphere from pollution. The impressive review given in last year's report of the Advisory Council of the twenty years work of the Food Investigation Board shows how important are the advances which have flowed from work initiated in 1917 in face of the serious shortage of food then existing. It is difficult indeed to assess the importance to our war effort of the increased knowledge gained in regard to the storage and transport of food of all classes. Victory might indeed turn on the elimination of waste in this manner by the preservation of existing stores or supplies from damage by disease or pests, but it may equally depend on the further increase in our resources coming from more effective utilization, through the Department, of the resources and knowledge already available for the elaboration and execution of a sound policy of food production and supply.

Great as have been the achievements of the Department and admirable the work of its numerous research stations, boards or sections, the nation cannot rest content with what has already been done. There are still industries which suffer from the absence of scientific direction and failure either to prosecute research or utilize existing scientific knowledge. Five years ago, the Advisory Council wrote in its report: "The scientific outlook of these industries leaves much to be desired. Neither in the directorates nor among the technical and executive staffs is sufficient weight yet given to scientific attainment and experience, and until a radical change has taken place in this respect the position is bound to be that the industries as a whole will remain unable to obtain the full benefit of the results of scientific investigation." The scale upon which research is organized, and even its extent in Great Britain, still compare unfavourably with that in some of its competitors, and it cannot yet be contended that with all the advances of the past twenty-five years the value of scientific research and its contribution to industrial progress or national welfare is generally appreciated either by the general public or by the Government.

The increased attention which is now being given to the general structure of the organization of research in Great Britain itself shows that the work of education has progressed. The twenty-five years' work of the Department will be considered not by itself but in relation to the research proceeding in industry, at the universities, and under more direct Government auspices, such as through the Agricultural Research Council or the Medical Research Council. If the expansion still required for the full service of the needs of individual industries or of national needs is to be secured, more than additional financial resources is required. There is still need for close co-ordination of existing effort, and for the re-distribution of available resources, whether of personnel or equipment. The lack of proportion between scientific advance in different fields is a handicap which requires correction and involves further attention to our educational system, possibly by more fundamental methods than the distribution of grants to students or research workers. Progress here depends on the education both of public opinion and of the administrator. We may well hope that, in glancing over the twenty-five years' work of the Department of Scientific and Industrial Research, scientific workers may be led to take a further part in that task of education and give firmer and more united support to the elaboration of a national policy and programme of scientific and industrial research which will serve the nation's changing and growing needs, whether in peace or war, on a more adequate scale.

SCIENCE IN THE ROYAL ACADEMY, 1940

BY LIEUT. W. E. SWINTON, R.N.V.R.

THE one hundred and seventy-second exhibition of the Royal Academy of Arts, which opened on May 6, is a typical "Royal Academy". That is to say, it is conservative and consists of the same kind of interesting, promising, or sometimes even satisfying works largely by the usual artists. Its subjects for the most part are retrospective, concerned with the personalities and events of the past rather than reflecting the tendencies and affairs of the present. It is therefore natural that the general tendency of the works is to portray the splendours of the seasons and those rural and coastal charms accessible to the country cottage rather than the stirring, if unpleasant, realities that confront us now. Artistic licence, however, like that of the poets, stipulates no adherence to the apparently stupendous events of the day, a fact which may explain why art is more enduring than the news-sheet.

There are, of course, a few works devoted to the more spectacular events of the last few months. Of these, pride of place goes to Norman Wilkinson's "River Plate Action", an inspiring representation based on the account given by Captain Woodhouse, R.N., and the same artist's "Air Battle, December 18th, 1939", painted from a description given by the leader of the formation. The *Altmark* incident is recalled by "The Stranded Prison-ship", by Charles Gere, R.A. "The Convoy and her Guard", by A. J. W. Burgess; "Suburbia, 1939", by C. R. W. Nevinson, A.R.A.; and "Retribution", the end of a U-boat, by Arthur Burgess, bear testimony to the less spectacular necessities of these times.

So far as strictly scientific activities are concerned, this exhibition is no more lavish than its predecessors. If the highways and byways of scientific endeavour have any artistic stimuli, it must be admitted that the results do not pass the strait gate of Burlington House. Of the seventeen hundred works now shown, only about ninety can be said to be even incidentally of scientific interest, and that is taking both science and the subjects of the pictures at a very wide estimate.

As usual, the botanists and the geologists have nearly all the spoils, largely because flowers are amongst the most convenient themes for both indoor and outdoor painting, and because, on the other hand, landscape painters of even the most modern school can scarcely avoid some hint of the geological background.

Agriculture, as in last year's exhibition, has one of the best pictures of the year, by that habitual author of 'best pictures', Dame Laura Knight. It is entitled "January, 1940", and depicts a land-girl at work in wintry surroundings.

Archæology is represented by Charles Oppenheimer's large and pleasing "Roman Wall, Northumberland", and by Mr. W. P. Robins's more topical "The Saxon Ship at Sutton Hoo". There is a score of castles from many parts of this and other countries, and in various stages of disrepair, which may also attract the antiquary, but space does not permit their catalogue here.

For the anthropologist there is a small number of pictures of distinguished artistry and origin. Negroes, Chinese and Gypsies are the favourite subjects: and of these Laura Knight's "The Gypsy" (purchased under the Chantrey Bequest); Sir John Lavery's "Gypsies in Ireland", a work painted some years ago; and the continuation of Mr. Gerald Kelly's charming Burmese studies must be mentioned.

For the botanist, or perhaps more accurately the flower-fancier, the Academy must be a delight. Art does more than memory, for it gives us roses all the year round. Here, there are roses in plenty, and lilies, pinks, cornflowers, cinerarias and tulips, "Spring Flowers", "June Flowers", "Summer Flowers", from anemones to zinnias. Trees there are, too, trees casting their cool and leafy shade, trees burdened with snow, and trees brilliant with blossom. Attractive and somewhat unexpected examples of the latter group are Mr. George Belcher's "Tugley Farm", with its contrast of summer sun and shade, and the luxuriant foliage of Mr. A. J. Munnings' "Drifting", a large and colourful canvas with a canoe on the limpid waters of a tree-shaded stream.

Geologists with imagination have an even richer field this year in which to exercise their fancy. Scottish scenery vies with the English moorland for pride of place, with coastal attractions of the south and the staccato splendour of the Alps following on; a variety which is happily knit by the versatility of Oliver Hall, R.A., who shows typical highland features in his "Bridge in Inverness-shire", the characters of its English counterpart in "Rothbury Moors, Northumberland", and supplies the continental contrast of a recently dissected plateau in "Ronda, Spain". A somewhat sharper contrast in topography is seen in the gently rounded features of the old landscape of "A Fifeshire Farm", by R. W. Stewart, and the jagged boldness of the "Dents du Midi" of the late Melton Fisher. "Winter in a Cotswold Village" (A. G. James) and "Winter in Perthshire" (McIntosh Patrick) are gentler variations of the same theme, to be compared with the sterner work of snow and ice visible in "Zermatt" by Mrs. Elwell. For a complete contrast there is the attractive panorama by Charles Gere, R.A., entitled "The Tidal Severn", with its well-displayed meanders. Typical cliff and coastal scenery, which is perhaps even more attractive to the field geologist, is supplied by Gerald Kelly in his "Golfo Tigulio, II"; in "Swanage", by R. R. Gill; and especially in "The Mewstone: Entrance to Dartmouth from Seaward", by Charles Pears.

Applied geology is represented only by "The Derelict", a tempera painting by Mr. Harry Allen, which shows an old quarry and its abandoned crusher.

Mineralogy is almost entirely unrepresented. Hitherto it has been safe to rely upon the jewelled richness of Gerald Brockhurst's portraits, but Mr Brockhurst is one of many academicians who have not exhibited this year. The meteorologists, too, must take what they can from a very few landscapes, of which Sir A. Brown's "A Passing Shower", with its thundery sky, and Bertram Priestman's "Storm Clouds, North Wales" call for special mention.

The important and attractive field of industry and engineering is unexpectedly neglected, although Alan Blyth's two topical pictures "Building an R.A.F. Aerodrome" and "Evening at an R.A.F. Aerodrome" do something to alleviate the deficiency.

The number of pictures of zoological interest is also smaller this year. Mr. Munnings' studies of racehorses as usual command attention, and Dame Laura Knight contributes a delightful scene of a quieter kind in her "Suffolk Mare and Foal". Miss Jessie Hodge also has a pleasant study of a swan with its chicks in "All Aboard!". Phillip Connard's "Pelicans", which has been bought for the Academy under the Chantrey Bequest, is of interest, as is Mrs. Daisy Smith's "Amherst's Pheasant". The farmyard aspect is supplied by "Gloucester Spots at Abnash", by J. A. Colquhoun Morrison.

"The Aviary", by James Fitton, is suggestive of a zoo; while "Painting the Air Balloon", a tempera by Ernest Dinkel, reveals a glimpse of the museum workshop.

There are several items of architectural interest for scientists: "Scaffolding at Winchester College, 1938"; "Canterbury Quad, Christchurch, Oxford"; "Hertford College Bridge, Oxford"; "The University of London, Interior of Great Hall"; "Goldsmiths' Library, University of London"; and an interesting model of the new University buildings in Bloomsbury by Charles Holden. There are also drawings and plans of the Courtauld Science and Art Block of Felsted School, and of the Garden Court Wing of the British Medical Association.

Portraits or statuary of scientific and university men are not numerous, but the few are worthy of attention. Pre-eminent among them is the splendid life-size painting of the late Lord Crawford by James Gunn, one of the best pictures in the exhibition. Augustus John celebrates his return with a fine portrait of the Hon. Vincent Massey; and Mr. R. G. Eves, R.A., has deposited as his diploma work his portrait of Sir Joseph Barcroft. The Rev. E. Schomberg, Master of Charterhouse (Ronald Gray), the late Dr. H. R. Rathbone (L. Campbell Taylor), and Sir Herbert Baker (A. K. Lawrence, R.A.) are other notable portraits. Physicians are well represented by Sir Robert Hutchison (James Gunn), the late Prof. Edward Mapother (A. R. Thomson, A.R.A.), and Dr. E. B. Gunson (James B. Manson). There is also a charming miniature of Dr. Cyril Horsford by his daughter.

Museum men will be pleased to see the miniature of Dr. Charles ffoulkes by Dorothy Garratt, and the sanguine by Robert Swan of Mr. F. W. Troup. Miss Helen Campbell has done a chalk study of Sir Dennison Ross.

Amongst the sculpture there must be mentioned the bronze bust of Lord Cadman (Donald Gilbert), the bronze bust of Sir David Milne-Watson (Eric Schilsky), and the model of a bronze memorial to Sir Archibald Denny (L. S. Merrifield). Miss Barbara Tribe has done an excellent bust of that distinguished soldier and master of Peterhouse, Lord Birdwood. Mr. Bertram Pegram exhibits a bust of Sir Daniel Lleufer Thomas, a welcome testimony to services to the University and National Museum of Wales, and Mrs. Bingguely-Lejeune has a bronze relief of that great patron of the sciences, Lord Nuffield.

DISTRIBUTION OF MARINE ORGANISMS

AT the general meeting of the Linnean Society of London on April 25, a discussion regarding the extent to which the distribution of marine organisms can be explained by, and is dependent on, the hydrographical conditions present in the great oceans was opened by Lieut.-Colonel R. B. Seymour Sewell.

After dealing with the main categories of marine organisms—plankton, nekton, and benthos—and defining the various types of plankton, Col. Sewell considered the ancient Tethys Sea and the effect of its subsequent closure on the distribution of corals. The view has often been advanced that species found to be limited to-day to the North Atlantic and northern part of the Indian Ocean are relics from this early Tertiary sea; but recent investigations have so greatly increased the number of these species that this explanation is unlikely. A study of the ancient group of Crinoids provides an alternative explanation, and suggests that, while some species have reached the Atlantic and Arctic Oceans from the centre of origin in the region of the Malay Archipelago through the Tethys Sea, others have been dispersed along lines which correspond closely with the surface and deep-water currents of the present day.

There can be no doubt that the character and direction of flow of marine currents have had a profound influence on the fauna and flora of different regions, and are sufficient to account for the frequency with which species are found to be cosmopolitan in their habitat. Further, the convergence zones set up in regions where the different current systems abut upon each other may provide temperature barriers across which only the most tolerant species are able to pass, and thus give us sharp boundary lines between two types of fauna or flora.

Detailed studies of various groups of animals and plants within the limits of a single ocean have produced an important body of evidence as to the correlation between the distribution of the organisms and the presence of water of a particular origin, as well as the direction and extent of flow of this water. This has been well shown in investigations on both phyto- and zoo-plankton of the North Atlantic, as well as on the diatoms of the Southern Ocean, and evidence is also accumulating that benthonic organisms may be affected in much the same way, as shown by recent work on sea-urchins, barnacles and sponges.

A study of the various zoogeographical regions which have been delimited as the result of work on the surface plankton reveals that these correspond fairly closely with the surface currents, and that the main line of dispersal for such plankton runs from east to west. A systematic study of the weed-haunting Harpacticid Copepods or of the surface-living Calanoids suggests that a very large percentage of the species of these crustaceans must have originated in the region of the Malay Archipelago, and that the farther we get away from this region the smaller is the number of Indo-Pacific species to be found, as might be expected if their dispersal is due to the surface currents. Similar evidence has been provided by the distribution of other groups of animals and of the littoral algæ.

In regard to the deeper levels, a study of the distribution of the meso-planktonic Calanoids again shows a distinct correlation with the general trend of the mid-water and deep currents. In this group the centre of origin appears to have been largely in the North Atlantic, and their distribution can be shown to follow the lines of the deep currents from west to east. Investigations on the Scyphomedusæ of the Indian Ocean suggest that these organisms have followed the same route, but we find that their distribution in the Indian Ocean is limited by the recently discovered azoic area in the Arabian basin and the Gulf of Oman. In this area, between depths of about 500 and 1,250 metres, there is a marked deficiency of oxygen, and the effect of this is well shown in the vertical distribution of two species of Calanoid copepods within and without the affected area.

With regard to the nekton and the benthos, the movements of the water masses must play a part in the dispersal of the eggs and larval stages while these are planktonic. The distances to which such forms can be carried by currents, however, will depend partly on the rapidity of the current and partly on the length of the larval period, but at the same time a study of the bottom topography reveals the presence of a number of 'stepping stones' by means of which a species could pass from one ocean to another in a series of successive generations.

In conclusion, Colonel Sewell pointed out that the cosmopolitan habitat of many species might well be accounted for by the influence of ocean currents on distribution. Further, a uniformity of the fauna and flora has not yet been achieved in spite of the long period of time that has elapsed since the oceans assumed their present positions and connexions in the middle of Tertiary times; nor can this be achieved while new forms continue to make their appearance. The ability of a given species to obtain a cosmopolitan range seems to depend to a great extent upon the ocean in which it made its original appearance.

Dr. Maurice Burton dealt with the distribution of marine sponges, and stressed the importance of sound systematics as a preliminary to zoo-geographical investigation. He agreed with Colonel Sewell as to the important part played by ocean currents in the dispersal of species, and pointed out that the distances reached depend to a great extent upon the duration of the larval life. The metamorphosis of a larval sponge on the surface film, which has been recorded under laboratory conditions, might well have a decided effect upon the dispersal of certain forms in the sea.

Dr. Anna Hastings considered the distribution of antarctic and subantarctic Cellularine Polyzoa. She showed that the distribution of the species is very closely related to hydrographic conditions, only 20 per cent of subantarctic and antarctic species being common to the two regions as limited hydrographically by the Antarctic Convergence. A similar separation is noticeable, and usually even more marked, in the few other groups of animals for which data have been obtained.

On the other hand, the distribution of the genera of antarctic Cellularine Polyzoa does not appear to be specially related to hydrological conditions. Their distribution points to eastern rather than western affinities, that is, with the Australasian, Malayan and Japanese faunas rather than American. This is also found in other groups, but not in the antarctic Echinoderms (D. D. John, 1937). These tendencies are difficult to relate to present hydrological conditions, and are more probably due to interrelations of the geological history of the region and the phylogeny of the groups.

Mr. J. R. Norman pointed out that fishes, being for the most part active swimmers, are not dependent upon the ocean currents for their distribution to nearly the same extent as the invertebrates already mentioned, although these may be an important factor in transporting pelagic eggs and larval stages, as in the case of the European eel. In the case of coastal fishes, including the littoral forms as well as those occurring at no great distance from the shores in water down to about 500 metres in depth, the most important hydrological factor influencing their distribution is the temperature of the sea. By taking the mean annual surface isotherms of 6° C., 12° C., and 20° C. respectively, it has proved possible to delimit a series of zones of distribution in the sea, each with its more or less peculiar types of fishes. For example, the distribution throughout the world of the genus Sardina has been shown to lie roughly within the area bounded by the isotherms of 12° and 20°. The isotherm of 12° runs very roughly to the mouth of the English Channel, and it is just here that such warm-water forms as the pilchard, anchovy and red mullet are replaced by the herring, cod and plaice, and other cold-water types. This is also near the southern limit of the salmon and trout as marine fishes.

The islands of Tristan da Cunha and St. Paul, lying in the southern Atlantic and the southern Indian Ocean respectively, are about 4,000 miles apart but situated more or less on the same mean annual surface isotherm : there are certain species of fish common to these islands but found nowhere else. The fact that the Antarctic Drift runs direct from one island to another may have been a factor in assisting the spread of these fishes. There are about 90–100 species of fishes commonly found in the Patagonian - Falkland Islands region, but only three of these are found at the island of South Georgia, a bare 800 miles away but separated by the Antarctic Convergence, corresponding closely to the isotherm of 6° C.

Of the oceanic fishes, the pelagic forms, although they appear to have on the whole a wider distribution than most coastal fishes, still seem to be limited mainly by temperature. In the case of the abyssal forms, the contour of the sea floor may play an important part in limiting their range, and it may be noted that the submarine ridge running from Scotland to Iceland and Greenland, less than 1,000 metres in depth, is the northern limit of the Macruridæ, the most characteristic family of bottom-living oceanic fishes. Our knowledge of the distribution of the bathypelagic fishes is still very incomplete, but it may be said that a number of them have a cosmopolitan range and that recent investigations have tended to add greatly to this number. Some of them are capable of extensive vertical migrations, and it may be that they are able to negotiate barriers which would be effective in limiting the spread of coastal fishes.

Dr. Stanley Kemp emphasized the importance to the general question of marine distribution of the comparative stability of species in the sea, and instanced the occurrence of identical species of fish and crustacea on both sides of the Isthmus of Panama in support of the view that species can remain identical over a long period of time. He thought that this would account for some of the instances of bipolarity, and mentioned a Euphausian common in the north and south but absent over a large stretch of the middle Atlantic. If species have remained unaltered for long periods of time, any arguments which base distribution upon existing ocean currents must be fallacious.

As an example of the adaptation of a planktonic fauna to hydrographical conditions Dr. Kemp mentioned the work of Mackintosh, who had shown that plankton at the time it approaches the Antarctic Convergence sinks to a deeper level and in this way is carried back to its proper habitat in the Antarctic. The deep-water prawns of the genus Acanthephyra, which are abundant in tropical and temperate parts of the oceans, have recently been investigated in detail, and have been found to have become differentiated in the various oceans. The species are separated by quite trivial characters (the number of spines on the telson), which are, however, astonishingly constant. One species in the Atlantic shows a widely discontinuous distribution.

Dr. G. P. Bidder wondered whether the length of the larval life was really so important a factor in the dispersal of sponges, and suggested that in the case of calcareous sponges these might be carried to new localities on the bottoms of ships. He pointed out that the largest and finest specimens found at Naples and Plymouth were collected from vessels anchored in harbour for a month or so.

Prof. W. Garstang suggested that an interesting approach to the problem as far as pelagic animals are concerned would be to tabulate the differences in distribution of those forms with large and small larval stages respectively.

OBITUARIES

Prof. Jules Schokalsky

THE distinguished Russian geographer Prof. Jules Schokalsky died in Leningrad on March 26 at the age of eighty-four. He was widely known throughout Europe and America, where he made many friends at international scientific gatherings. As a boy he lived much in the country and acquired a love of Nature by his comradeship with a son of the poet Pushkin, and this æsthetic sentiment opened the way to serious scientific study. He led a life of ceaseless activity from the time he entered the Naval School at St. Petersburg in 1874 until his death, and for forty-five years I have had the privilege of enjoying his helpful friendship. Even the shock of the Russian revolution of 1917 did not check the continuity of his work; to him science was superior to politics. He continued under the Soviet system in Leningrad to give full expression to the enthusiasm for oceanography and cartography which had animated him during half a century under the Empire.

Schokalsky studied at the Naval School in St. Petersburg, and in 1877 he went to sea as a midshipman in the Imperial Navy. After two years he turned to shore work connected with naval research and education, spending three years at the National Physical Observatory under the great meteorologist, Dr. H. Wild. After this he joined the teaching staff at the Naval Academy and was professor and then emeritus professor of physical geography, meteorology and oceanography from 1910 until 1930. For a time he was librarian of the Central Library of the Russian Admiralty, and he ended his academic career and his life as professor in the University of Leningrad. He found time for innumerable honorary appointments, culminating in the presidency of the Imperial Russian Geographical Society, which he held for many years, and on his retirement was appointed honorary president of the same Society under the U.S.S.R.

He was a tireless writer with nearly five hundred entries of publications under his name, many of them, of course, being official reports, summaries and criticisms. His most important book was the "Treatise on Oceanography", in Russian, published in 1917. This is a work of originality and distinction, showing much ingenuity in the design of illustrative diagrams. He produced or edited with valuable introductions many atlases of the physical features of Russia. He paid special attention to hypometrical work and completed a map of the altitudes of European Russia in six sheets on the scale of 1 : 2,500,000.

Schokalsky planned and carried out an important series of researches on the temperature regime of Lake Ladoga during the years 1897–1902. The supreme contribution which he made to oceanography was the organization of physical investigations in the Black Sea. This was carried out under his personal leadership during 1924–27 in conditions of much difficulty and even privation. The result was to throw new light on the remarkable physical and chemical changes proceeding in the lifeless deep water of this anomalous land-locked basin. A special feature of the work was the collection for the first time of very long cores of deep-sea deposits; the length of these ranged up to one and a half metres.

Prof. Schokalsky had much charm of manner and great kindness of heart combined with dignity and a fine sense of honour. He made himself welcome wherever he went despite the deafness which latterly grew upon him. His later years were cheered by the companionship of a devoted daughter, herself distinguished in the modern science of soil analysis.

Hugh Robert Mill.

Sir James Mackenna, C.I.E.

Sir James Mackenna, who died on April 3, aged sixty-seven, belonged to the small band of members of the Indian Civil Service who, though not scientific workers themselves, employed their long service in India in encouraging the application of science to the solution of the agricultural problems of the country. I first met him in 1904, when he had been some ten years in Burma and was already recognized as one of the most successful directors of agriculture of his time. Even then he showed those qualities which distinguished him throughout his career—a thorough grasp of the problems of rural development, a strong belief that agricultural research was likely to lead to a great improvement in Indian crops and stock, and a faculty for getting things done. From this time on, his work as a member of the Indian Civil Service was chiefly concerned with agricultural development in Burma, until he was appointed agricultural adviser to the Government of India in 1916.

Mackenna's work in the last-named position was of outstanding importance. On his recommendation, two committees were appointed to consider, respectively, cotton and sugar production in India in all their aspects, and the results on the development of these industries have been very great. The former committee, among other things, recommended the establishment of the first self-supporting research organization for a purely Indian industry, and the existence of the Indian Central Cotton Committee, a permanent body with ample funds which controls research on cotton problems throughout India, has been very much of a landmark in the later agricultural history in India. Similar bodies have more recently been formed in connexion with other industries, but the idea came from the Mackenna Committee, and was probably the idea of Mackenna himself.

In 1920 he went back to Burma, and for the next five years he was the life and soul of many development projects which date from that period. After retirement to England in 1925, he was almost at once appointed a member of the Royal Commission on Agriculture in India, and toured the country again between 1926 and 1928. The chief result of that Commission has been the establishment of the Imperial Council of Agricultural Research and it is impossible not to see Mackenna's hand in a good deal of the organization of that Council, which has become the centre of scientific activity in connexion with Indian agriculture.

After his final retirement from India, Mackenna continued his interest in scientific work, especially as concerns Indian agriculture. He remained active to the end and was still the same inspiring personality as he had been in his prime. His principal claim to scientific recognition is that he never ceased to use the strong influence which he could exert, for the encouragement of research, while he had the faculty of inspiring those who were entrusted with the carrying out of the work which he had in mind.

H. H. Mann.

Sir Gilbert Barling, Bart.

Sir Gilbert Barling, Bart., died suddenly of heart failure at his home in Edgbaston on April 27, within three days of his eighty-fifth birthday. Sir Gilbert was the second vice-chancellor (afterwards pro-chancellor) of the University of Birmingham which he served for twenty years, having succeeded Charles Gabriel Beale in that office in 1913. From 1913 until 1933 he gave invaluable service to the University, which derived great benefit from his forceful personality and his unremitting personal devotion to its interests. Himself actively interested in outdoor sports, he did much to encourage the athletic side of university education. At the annual meeting of the Birmingham United Hospital, only a week before his death, Sir Gilbert was presented with an address of congratulation on completing sixty years of strenuous service to the hospitals of Birmingham.

We regret to announce the following deaths:

Mr. Owen Cattell, director of the annual exhibition of the American Association, assistant to the editor of *Science*, on March 26, aged forty-two.

Prof. Alexandre Desgrez, emeritus professor of medical chemistry in the University of Paris, aged seventy-six.

Captain E. E. M. Joyce, the well-known Antarctic explorer, on April 2, aged sixty-five.

Mr. G. W. Partridge, a pioneer of electricity supply, on May 3.

NEWS AND VIEWS

André-Jean Marie Brochant de Villiers (1772–1840)

ON May 16 occurs the centenary of the death of the French geologist and mineralogist Brochant de Villiers, through whose initiative the construction of a complete geological chart of France was undertaken. Born at the Château de Villiers, near Mantes, on August 6, 1772, he was educated under the Oratoriens and acquired a taste for natural history. When nineteen, he went to Freiburg, in Germany, to study under Werner, by whom he was much influenced. In 1793, when the Revolutionary movement in France was at its height, he entered the École des Ponts et Chaussées and afterwards the École des Mines. In 1804, when the École des Mines had been removed to Pezay, in Savoy, Brochant de Villiers was made professor of geology and mineralogy, and he held this post for some years after the return of the school to Paris in 1815. He also became an inspector-general of mines and a member of the Paris Academy of Sciences.

So early as 1811, Brochant de Villiers had submitted a plan for a chart of France, but it was not until 1822, when a copy of Greenough's geological map of England was received in Paris, that any definite steps were taken to further his plan. That year, however, he was entrusted with the construction of geological charts for the whole of France, and with his two assistants, Elie de Beaumont and Dufrenoy, he visited England to become acquainted with British methods of geological surveying. With the help of the engineers of the Corps of Mines, steady progress was made, and by 1835, fifty-nine charts of various districts had been prepared, but Brochant did not live to see the first complete map, which was published in 1842. This map was on a scale of 1 in 500,000, but the geological chart of France undertaken later, and completed only a short time since, is on a scale of 1 in 80,000.

Leopoldo Maggi (1840–1906)

LEOPOLDO MAGGI, an eminent Italian protozoologist and craniologist, was born at Varese, on May 15, 1840. He was educated at Pavia, where he was assistant first to Paolo Panceri and then to Balsamo Crivelli, and in 1864 was appointed lecturer in mineralogy and geology. In 1874 he was appointed professor of zoology and comparative anatomy and physiology at Pavia, and afterwards, when zoology became a separate subject, he occupied the chair of comparatve anatomy and physiology from 1875 until his death. He carried out studies in palæontology as well as various zoological and anatomical researches, but his principal work was concerned with protistology and craniology. He was the first Italian to direct attention to Protozoa, to the knowledge of which he made important contributions. His chief publications were as follows: "Nuovi orizzonti della protistologia medica" (1884), "A proposito dei protisti colerigeni" (1885), "I piccoli benefattori dell'umanita" (1886), "Intorno alla determinazione della specie batteriche secondo Pflügge" and "I microbi vantaggiosi all'uomo" (1888). He died on March 7, 1905.

International Spirit in Science

THE award to Sir Harold Carpenter of the Honda Prize was announced in NATURE of March 30. It is of interest to know that this is the second occasion only when the prize has been awarded. The first award was to Prof. K. Honda himself, in whose honour the Japanese Institute of Metals established the prize a short time ago. Prof. Honda's work on the magnetic and other properties of metals is well known to scientific men in many countries outside Japan. It is a striking tribute to the international feeling among men of science that the Japanese Institute of Metals should have chosen, at the present time, a British scientific man as the recipient of what may be regarded as the first 'open' award of its highest honour. During the Napoleonic Wars a century ago, it was possible for scientific men, even those in belligerent countries, to maintain fairly free intercourse and to obtain safe conducts for visits. To-day, the difficulties of the international situation have made such relations most difficult, and the recent recognition by the Japanese of Sir Harold Carpenter's achievements is thus doubly precious.

The Pharmaceutical Society: Honorary Members

IT will be gratifying to medical circles in India to learn that Colonel Ram Nath Chopra, head of the Faculty of Pharmacology in the School of Tropical Medicine, Calcutta, has been elected an honorary member of the Pharmaceutical Society of Great Britain. This distinction is conferred upon a very limited number of scientific workers, the list of honorary members being not more than twenty-five at the present time. Colonel Chopra has been, and still is, an earnest worker in the cause of reform of the drug trade in India; it was upon the recommendations of the Drugs Enquiry Committee, of which he was chairman, that the Indian Drug Bill, the provisions of which measure were commented upon in a recent issue of NATURE (May 4, p. 716), were based. At the May meeting of the Council of the Pharmaceutical Society at which the election took place, two other names were also added to the list of honorary members: Sir Ernley Blackwell, who was chairman of the Society's Statutory Committee during 1934–1939, and Sir William Willcox, the Visitor for the Privy Council to the Society's Examinations.

Nuclear Fission of Separated Uranium Isotopes

SOME recent accounts in the daily Press referring to the separation of uranium (235) would suggest developments arising from a letter in the *Physical*

Review (57, 546), by Dr. A. O. Nier. Nier there describes fission experiments conducted with small quantities of ^{235}U and ^{238}U separated by deposition in a mass-spectrograph. The masses of ^{238}U samples were of the order of 10^{-7} gm. and those of the ^{235}U samples about 10^{-9} gm. The samples were bombarded with slow neutrons obtained originally from a cyclotron. Fission products were observed in an ionization chamber when the ^{235}U isotope was used, but not with the more abundant ^{238}U. The ^{234}U isotope was not separated from ^{235}U, but its abundance is very small. It seems almost certain that ^{235}U is responsible for the slow neutron fission, as predicted theoretically by Bohr and Wheeler.

Shining in Human Eyes

From time to time, reports have appeared of the occurrence in human eyes of the phenomenon of "night-shining", which as was indicated in a recent paragraph (Nature, March 30, p. 506) has been observed in many animals by Ernest P. Walker, assistant director of the National Park of the Smithsonian Institution. It was there stated that Mr. Walker had no definite proof of such cases, although he had encountered reports of them. That statement has led Denis G. A. Dyson, King Edward VI School, Stratford-on-Avon, to write saying that for many years he has known of an "undoubted case" of shining eyes in a shop assistant in Birmingham. Although, not being aware of the rarity of such an occurrence he made no particular observations, his impression is that the glow was of a "dark red colour". In view of the apparent lack of information about such a condition in human beings, it would be of interest if some scientific worker could follow up Mr. Dyson's clue.

War-time Ventilation Problems

The question of ventilation is demanding special attention as the warm weather approaches. Mr. A. Peel's article on "War-Time Ventilation", published in the *Electrical Times* of April 18, is therefore a timely one. Special attention has to be paid to factories, mills, offices, etc., where a large number of people occupy one enclosure. It is an annual problem the solution of which in peace time is not always adopted as soon as it should be. Now certain factors due entirely to the War have greatly aggravated the working conditions in many factories and sometimes added very definite causes of bad ventilation. So far as 'black-out' is concerned, the Government insists that the obscuration must be complete. Whatever form this takes, the blacking-out process is responsible for a marked deterioration compared with the natural ventilation existing before the black-out. Many firms who were obliged hurriedly to arrange their black-out schemes and did so by painting windows or sealing them up by fitting wooden or metal shutters, or in other semi-permanent ways, have already had to strip this material away from windows. This has been necessary in order to get back to something like normal operating conditions as an alternative to serious labour trouble on account of high sickness rates, due to continuous working in artificial light and with poor ventilation.

The proper solution of some of these war-time ventilation problems may involve only the fitting of a small propeller fan or even the opening of all the windows. In other cases it will be essential to use a complete air-conditioning plant whereby a factory or section of a works may operate for twenty-four hours a day all the year round under constant conditions of temperature and humidity, and with an ample supply of clean fresh air to meet all the requirements of the personnel and of the process carried on. Between these two extremes there will be numerous combinations and modifications of method, and every case has to be studied on its own merits. Complete air-conditioning plant is already in operation in Great Britain in certain sections of the following industries: textiles, printing, biscuit and chocolate manufacture, pharmaceutical chemicals, food manufacture and packing, optical and other fine instrument making, and grinding wheel manufacture. In addition, complete air conditioning is also successfully and economically used for offices and other important rooms. By means of a well-designed plant it is possible to provide in a given space almost any combination of dry bulb temperature and relative humidity. Many different combinations of temperature and humidity are used in practice. Anything which can be done to reduce the variation of heat and moisture load and so cut down the total amount of heat to be dissipated will result in smaller and less costly equipment.

Criminal Anthropology in the U.S.A.

The crime wave of appalling dimensions, accompanied by a vast increase in organized crime, which appeared in the United States of America in the years following on the War of 1914–18, continues to constitute one of the gravest of the social problems of State and Federal administration, notwithstanding the repeal of prohibition, which offered an almost unlimited field for illicit gain. In consequence, attention has been directed once more to the possibility of segregating the potential as well as the actual criminal through a method of detection depending upon an anthropometric examination which would weed out or mark down individuals who in their physical characters showed traits characteristic of a criminal type. When crudely stated, this suggests a reversion to the ideas in criminology held by C. Lombroso in the later years of the last century, which anthropologists believed had been laid to rest when it was shown to general satisfaction that no distinctive criminal type could be said to exist. Nevertheless, a vast survey of criminal anthropology in the United States has been instituted under the ægis of the Division for the Examination of Prisons of the Massachusetts Department of Mental Diseases. It has been carried out by Prof. Earnest A. Hooton of Harvard University, with the assistance of a body of field-workers and statisticians.

The dimensions of the investigation may be gauged from the fact that the case material for native white prisoners consists of 4,212 individuals; and foreign, foreign born, negro and negroid criminals were treated on the same scale. Dr. Aleš Hrdlička has been moved by the discussion to revive and review material which he collected more than forty years ago, when the question was previously under discussion (*J. Criminal Psychopathology*, 1, 2; 1939). In 1897–99, the New York Juvenile Asylum contained 1,000 inmates of both sexes, 5–16 years of age, of whom 77 were criminal or vicious, and 61 were the offspring of criminal, insane, intemperate or dissolute parents. Anthropometric measurement of each child in the institution showed that the transgressors could not be separated physically from the remainder, or probably from similar classes outside. Apart from their conduct they could not have been recognized as criminal. Of the children of the intemperate and other undesirables, however, it was found that almost 60 per cent were "inferior in their principal measurements to the general averages of the corresponding class of the asylum children", or subnormal. Dr. Hrdlička's conclusion, therefore, is that it is "hopeless to expect that anthropometry and physical examination can ever aid in this detection".

Malting Barley

THE agricultural data derived from five conferences on malting barley held at Rothamsted Experimental Station in the years 1934–38 have been described and discussed by H. V. Garner and J. W. Weil (*Empire J. Exp. Agric.*, 8, 65). More than a thousand samples of English malting barley were sent in by growers from the more important barley-growing districts, grading being carried out by the Valuation Committee of the Institute of Brewing. Six malting grades were distinguished, three for pale-ale and three for mild-ale barleys, the largest number always falling into the latter groups. Spratt Archer and Plumage Archer were by the far the most popular varieties, and their stiffer straws had encouraged generous manuring. Autumn-sown crops usually proved superior in quality but inferior in yield to the spring-sown barleys of the same district and year, and early sowing was generally found to improve the quality in the latter case.

The effect of the crop preceding the barley was also examined. Sugar beet predominated in Norfolk and Suffolk, and in other districts, including Yorkshire, Lincolnshire and the West, folding roots were frequent, whereas elsewhere a cereal crop was more usually taken. Yield was greater after sugar beet or roots than after corn, in spite of the heavier manuring usually given to the straw crop. Lodged crops yielded more than those which were standing, but the quality of the grain was slightly depressed. Analysis was also made of the inter-relationship between soil, season and quality.

Hygiene of Swimming Baths

IN his inaugural thesis (*Thèse de Paris* 1940, No. 17), Dr. Marcel Mazillier remarks that it has been known from remote antiquity that certain diseases may be spread by swimming baths, as is shown by the fact that admission to them was forbidden to lepers and others suffering from contagious diseases. The micro-organisms found in the water of bathing places are numerous and of various kinds, the water becoming rapidly contaminated by bacteria derived from the mouth, nose, fæces and urine of the bathers. The diseases contracted in swimming baths chiefly affect the throat, ears and eyes. Cases of spirochætal jaundice, in which the disease may be localized in the meninges, may occur as well as skin diseases, especially that known as 'athletes' foot'. It is therefore important that in constructing a swimming bath care should be taken so far as possible to eliminate causes of contamination, whether derived from the bather himself, who should give himself a douch before entering the bath, the water used for washing out the bath, or other sources. Provision must also be made for the proper heating, ventilating and lighting of the establishment. The drinking water, which must possess all the requisite qualities, may be purified by ultra-violet rays, though this is rather a difficult and expensive process, or by the addition of bactericidal chemical products such as chlorine and its derivatives, colloidal metals and ozone.

Tung Oil

THE supply of tung oil has been so profoundly affected by the war in China that considerable interest is attached to a report by Dr. M. Ashby upon his tour of the area in the United States in which the tung tree is now being cultivated (*Bull. Imperial Inst.*, 38, No. 1; 1940). It is estimated that some 175,000 acres in the States bordering on the Gulf of Mexico now carry plantations of this tree, but many earlier plantations were on land that has since proved unsuitable, the great difficulty proving to be frost damage. The species cultivated is almost exclusively *Aleurites fordii* Hemsl.

Details are given of cultivation, harvesting and mill treatment of the crop, etc., and it is clear that a very high-grade quality of oil can thus be obtained, but until 1938 the yield had been uncertain owing to frost damage. Although three million pounds of tung oil were produced in the States in 1938 (against an import of 108 millions in that year), until now the paint and varnish industry practically bases itself upon the Chinese supply, though the war has made this a very uncertain source.

Cinchona Production in the Netherland Indies

AN article by Dr. M. Kerbosch in the *Bulletin of the Colonial Institute of Amsterdam* (3, No. 1, December 1939) gives some notes on cinchona culture and the world consumption of quinine. Existing plantations in the Netherlands Indies could produce considerably more than the present world consumption. The Netherlands Indies Government has at its disposal sufficient guarantees to prevent the agreement between the manufacturers and producers being used in a way which would hamper malaria control. Cinchona growers would welcome the opportunity to increase their output, and the agreement, which has united practically all producers and manufacturers, makes it possible to put regularly at the disposal of malarial areas large quantities of quinine for longer periods. Obstacles to the use of this superabundance of the Java cinchona estates are largely financial and technical. Disbursements for defence in all countries cripple other projects, including health or hygienic measures. In addition, malaria control with quinine requires an efficient administrative machine for the distribution of the drug under medical supervision. For mass treatment of malaria, quinine is unlikely to be replaced by other cinchona alkaloids or synthetic drugs.

United States National Museum

THE report of the United States National Museum for 1939 is a stimulating document, particularly in the evidence it contains of widespread activities in exploration and field work. No fewer than fifteen expeditions or trips were made, mostly to chosen localities in the United States, but also to regions ranging from the South Pacific Ocean to Alaska and West Greenland, for the collection of data or specimens bearing upon archæology, anthropology, stratigraphic palæontology, and animal and plant distribution. Specially noteworthy seem to have been the results of Dr. Hrdlička's tenth visit to Alaska and the Aleutian Islands, where many skeletons and artefacts of a pre-Aleut stock were collected. The educational activities of the Museum, apart from the usual special exhibits, fourteen of which ran almost continuously throughout the year, include an admirable scheme for the allocation of duplicates to schools and other institutions, which benefited to the extent of 3,293 specimens. Exchanges involved the dispersal of 13,362 specimens, and it is gratifying to note that the British Museum (Natural History) was a very active partner in this useful form of scientific co-operation. The catalogues of the various departments now record the collections as containing more than 16 million specimens. The popularity of the exhibition galleries is indicated by the total of 2,233,345 individuals who visited the various Museum buildings, and a glance at the monthly lists shows that the holiday periods of April and August afford welcome opportunities to visitors. The cost of running the Museum during the year was 771,880 dollars.

Rabies Treatment in Southern India

THE annual report of the director, Lieut.-Colonel Iyengar, for 1938 of the Pasteur Institute of Southern India, Coonoor, surveys the anti-rabic treatment given at the Institute and the subsidiary treatment centres during the year. A total of 12,396 persons were treated at the Institute and centres during the year, with twenty-one deaths, a mortality rate of 0·17 per cent. Animals to the number of 561 were also treated. Paris fixed virus, now in its 1,011th passage, was used in the preparation of the vaccine, which consisted of a 5 per cent carbolized sheep-brain suspension prepared by Semple's method. Under research work, experiments were carried out on the cultivation of the rabies virus. Attempts to culture the rabies virus on the chorio-allantoic membrane of the developing hen's egg, so useful for propagation of some viruses, were unsuccessful. In media containing chick embryo brain, propagation of the virus was apparently attained, though the method does not promise to be of much practical importance.

Medical Research in Egypt

THE fifth annual report of the Research Institute and the Endemic Diseases Hospitals, Cairo, by the director, Dr. M. Khalil Bey, contains a summary of the reports of the scientific sections and the clinical reports, including investigations on Egyptian splenomegaly, anæmias and various parasitic affections. A report is also included of the work of the Khanka Malaria Research Station. This gives the results of a mosquito survey of the area, with the species of mosquitoes found, and a description of some of the preventive measures undertaken. These include drainage, filling up of water holes and clearance of water-weeds in places. Breeding places of mosquitoes are treated with Paris green when there are Anophelines only, or with mazout oil if Culex larvæ are also present. In future, the Institute will be named the "Fouad the First Institute and Hospital for Tropical Diseases".

Bermuda Seismograph Station

IT is reported in *Earthquake Notes* (11, No. 4; April 1940) that through the co-operative effort of the Bermuda authorities, the Woods Hole Oceanographic Institute, the United States Coast and Geodetic Survey and Dr. George P. Woollard of Princeton University, the second component of the Milne-Shaw seismograph at Bermuda has been installed, the first records being obtained on December 10, 1939. The significance of this station is not only that earthquakes in eastern North America and the West Indies will be located more accurately, but also satisfactory studies of wave transmission over all mid-Atlantic paths have become possible. The position of this St. Georges, Bermuda, meteorological and seismological station is latitude 32° 22′ 47″ N., longitude 64° 40′ 57″ W., elevation 136 ft.; Mr. C. P. Bartram is in charge.

British Empire Naturalists' Association

THE British Empire Naturalists' Association announces the retirement of its honorary general secretary, Mrs. G. B. Thomason, which took place at the end of April after thirty-five years work. She is a niece of E. K. Robinson, who founded the B.E.N.A., and has been responsible for most of the routine business work of the Association. It is also announced that plans have been made to hold the usual B.E.N.A. summer gathering in the first fortnight of June, and the Ludlow district has been selected: local arrangements will be put in the hands of the Shropshire Branch, and, despite the War, the local interests of fauna, flora and scenery are hoped to attract a good attendance.

Summer School in Social Biology

THE Educational Advisory Board of the British Social Hygiene Council is arranging a summer school for teachers to be held at Westminster College, Cambridge, during August 1–8. The school is to focus on "Social Biology in the School: War-time Problems". The services of distinguished speakers are being secured. A series of symposia is also being arranged, at which teachers will be invited to express their views. Further particulars can be obtained from the Education Officer, Educational Advisory Board, Tavistock House South, Tavistock Square, London, W.C.1.

International Congress of the History of Sciences

THE fifth International Congress of the History of Sciences will be held at Lausanne next September if the political and social conditions of Europe permit. M. Aldo Mielli, the perpetual secretary of the International Academy of the History of Sciences, having now settled at Santa Fé in the Argentine Republic, as director of the history of sciences at Santa Fé University, M. J. A. Vollgraf of Leyden has been appointed assistant secretary for Europe and the Mediterranean countries. The review *Archeion*, the official organ of the Academy, will henceforth be published at Santa Fé instead of at Rome as hitherto.

National Research Council of Canada: Awards

SIXTY-SIX Canadian university students will take training in research in Canadian institutions under National Research Council Scholarships during 1940–41. While the majority of these students will be engaged in chemical and physical investigations, such biological studies as genetics, plant pathology, physiology and zoology will each have a quota of students. Two Special Scholarships of 1,000 dollars each will be held in the Division of Chemistry at the National Research Council laboratories, by R. L. Cunningham and R. B. Harvey of McGill University. Four Fellowships of the value of 750 dollars each, and thirty-seven Studentships of the value of 650 dollars each, will be held at Canadian universities directly under the auspices of the National Research Council. With the co-operation of Canadian universities, the National Research Council is also awarding twenty-three bursaries of 250 dollars each. These bursaries are available to students of high attainments who have just graduated and are ready to take their preliminary training in research.

Announcements

ON May 19, 1939, the seventieth anniversary of his birth (see NATURE, **143**, 813, May 13, 1939), a number of Prof. Henry H. Dixon's friends, colleagues and students presented him with an address expressing their regard for him and appreciation of his work. This address, with more than seven hundred signatures, beautifully bound, has now been handed to Prof. Dixon, and he asks us to convey his sincere thanks to all who shared in doing him this honour.

PROF. J. C. DRUMMOND, scientific adviser to the Ministry of Food, will give an informal luncheon talk at the Chemical Club, 2 Whitehall Court, London, S.W.1, on May 20. He will take as his subject "Essentials of Wartime Diet".

FIVE members of the Ling Physical Education Association have received decorations awarded by the Fédération Internationale de Gymnastique Ling in recognition of their services on behalf of physical education: they are Miss M. Stansfeld, principal of the Bedford Physical Training College; Miss M. Fountain, principal of the Chelsea College of Physical Education; Miss P. Spafford, secretary of the Ling Physical Education Association; Mr. F. Punchard, Scottish secretary of physical education, Jordan Hill; and Mr. K. Rofer, author of several books on physical education.

DR. J. W. LLOYD has been appointed acting head of the Department of Horticulture in the College of Agriculture, University of Illinois, to succeed J. C. Blair, who founded the department thirty-nine years ago. Dr. Lloyd, who has worked on the staff for many years, has directed research on fruit and vegetable crops.

DR. DETLEY W. BRONK, director of the Eldridge R. Johnson Foundation for Medical Physics and of the Institute of Neurology, University of Pennsylvania School of Medicine, has been appointed managing editor of the *Journal of Cellular and Comparative Physiology* of the Wistar Institute of Anatomy and Biology in succession to Edmund Newton Harvey, of Princeton University.

THE Pan-American Congress of Tuberculosis will be held at Buenos Aires and Córdoba during October 13–17 under the presidency of Prof. Gumersindo Sayago. Further information can be obtained from the general secretary, Dr. Raúl Denis, Calle Pasteur 346, Buenos Aires.

THE lowest maternal mortality ever recorded in the United States—43·5 per 10,000 live births—has recently been recorded by the United States Bureau of the Census for the year 1938. For the first time on record less than 10,000 (9,953) deaths were assigned to puerperal causes.

ACCORDING to an official report there are at present 1,941 foreign students in German universities representing the following countries: Bulgaria, 532; Norway, 142; Greece, 101; with Yugoslavia, Italy, China, the Baltic States, the Scandinavian countries and the United States showing small numbers.

WITH its February issue the *Journal of Contraception* was renamed *Human Fertility*; it will continue to be issued under the auspices of the Birth Control Federation of America.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 749. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Relation between Breaking and Melting

IN a recent paper[1], M. Born has given a new theory of the melting of crystals which is in good agreement with the experimental facts. The stability conditions of a lattice at a certain temperature and a certain uniform pressure for arbitrary small homogeneous deformations are derived, and it is stated that melting will take place when, on raising the temperature, at least one of these conditions is violated. In another paper by Prof. Born and myself to be published shortly, an attempt is made to calculate the tensile strength of a crystal at zero temperature. Here again, the stability conditions of the lattice, stressed in the direction of one of the axes, against any small homogeneous deformation, are derived, and the crystal is supposed to break if one of these conditions is violated. Thus a close relation between the two phenomena of melting and breaking seems to exist, melting being nothing else than a breaking due to the action of the heat movement of the atoms; or putting it the other way round, breaking is nothing else than melting enforced by the action of the stress. Unfortunately, the theory mentioned above, like other former theories, gives results not in agreement with experiment: the tensile strength as well as the critical deformations calculated from this theory with plausible assumptions are about a hundred times larger than the real values given by experiment.

Now, one of the results of the theory of breaking is that the tensile strength should be of the order of magnitude of the heat of sublimation per unit of volume. But, as a consequence of what is said above about a connexion between breaking and melting, one would expect a connexion between the tensile strength and the heat of melting rather than the heat of sublimation. Indeed, comparing the experimental values, one can see immediately that the tensile strength is of the same order of magnitude as the heat of melting per unit of volume. This observation has led me to consider the connexion between these two quantities more thoroughly, and I have succeeded in deriving an equation from which the tensile strength F of an isotropic body at low temperature can be calculated exactly, if the melting heat Q (per unit of mass), the density (ρ), and the Poisson constant (μ) of the substance are known. This theory and a number of other considerations concerning Born's theory of melting and the thermodynamics of crystals, and other relations between melting and breaking will be published shortly.

The main idea of the theory is that one has to compare two 'states' of a system: (1) the uniformly stressed rod with a volume $V + \delta V$, and a certain potential energy U distributed uniformly over the whole rod; and (2) the rod just before it is broken, the energy U concentrated in the volume δV and melting the matter in it, and the rest of the matter unstressed and with no potential energy. The condition for breaking is that the energies of these two states should be equal. The external conditions must be chosen so as to prevent movement of the broken pieces and to allow of an exact energy balance, including the device for the production of the breaking force. In this way one gets the equation:

$$F = Q\rho\,\frac{1-2\,\mu}{3-5\,\mu}.$$

In the following table the experimental values of the tensile strength, extrapolated to very low temperatures, together with the values of Q, ρ, and μ are tabulated for all elements for which experimental data for the dependence of tensile strength on the temperature were available.

Element	$F \times 10^{-2}$(kgm./cm.^{2})	Q(cal./gm.)	ϱ	μ	$\frac{Q\varrho}{F}\frac{1-2\mu}{3-5\mu}$
Ag	29	25	10·5	0·38	0·85
Al	23	90	2·7	0·345	1·1
Au	27	16	19·3	0·42	0·89
Cu	32	50	8·9	0·35	1·4
Fe	80	66	7·8	0·28	0·75
Ni	55	63	8·8	0·31	1·2
Pb	4	6	11·3	0·445	1·03
Pt	34	27	21·4	0·385	1·6
Sn	12	14	7·3	0·33	1·08
Zn	30	26	7·1	0·33	0·66

The last column gives the values of $\frac{Q\rho}{F}\,\frac{1-2\,\mu}{3-5\,\mu}$, which quantity should equal unity, if our formula is correct. The average value is 1·065 and the mean deviation from that average 0·255, which is not larger than the uncertainty of the experimental values. The mean error of the average is accordingly 0·085, and the deviation of the average from unity is within the experimental error. Thus the theory is in perfect agreement with the experimental facts.

R. FÜRTH.

Department of Applied Mathematics,
University of Edinburgh.

---

[1] Born, M., *J. Chem. Phys.*, **7**, 591 (1939).

THE most important and conspicuous property of matter, namely, the strength of solid materials, the fundamental quantity for building, engineering and textile industries, has been hitherto completely unexplained; Prof. Fürth's results should remove physics from this embarrassing situation.

Quite apart from the theory, Fürth's empirical result, that magnitude of tensile strength and heat of melting are of the same order, is new and surprising. His formula expresses this relation quantitatively with the help of Poisson's elastic constant and is in perfect agreement with the experimental data available. The theoretical derivation uses a kind of thermodynamical equilibrium which differs from the usual methods; this is due to the fact that a solid under stress is not a genuine statistical equilibrium. This question needs further investigation though one can scarcely doubt the correctness of the resultant formula. The view due to Smekal that breaking strength belongs to the structure-sensitive (*struktur-empfindlich*) properties of solids must be abandoned, since it can be derived by thermodynamical reasoning without even mentioning atomic structure.

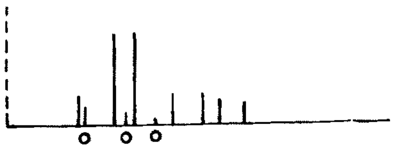
An Electron Diffraction Study of the Surfaces of Alkali and Alkaline Earth Metals Exposed to Air

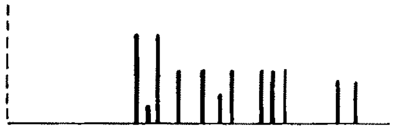
The most corrodible metals are those of the alkali and the alkaline earth groups. The products forming on a freshly cut surface of these metals on exposure to air were studied.

A fresh clean surface of lithium was allowed to stand in air for about five minutes. The diffraction pattern obtained from such a surface clearly showed the formation of lithium oxide (Li_2O) mixed with a small amount of lithium hydroxide.

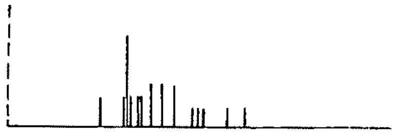
The pattern obtained from the surface of sodium similarly treated showed the formation of sodium bicarbonate; a micro-chemical analysis also verified the presence of the CO_3^{--} radical.



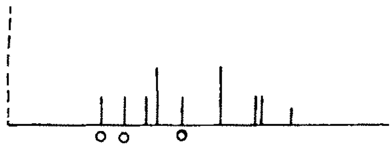
Diffraction pattern from lithium specimen. o, LiOH; other lines, Li_2O.



Pattern from sodium specimen, showing mainly the existence of $NaHCO_3$.



Pattern from potassium specimen, showing mainly the existence of $KHCO_3$.



The pattern from calcium specimen. o, Ca; other lines, CaO.

The formation of potassium bicarbonate on the surface of potassium in similar circumstances also occurs, but in this case the diffraction rings are sharper than those of sodium bicarbonate on sodium; this suggests that the reaction producing potassium bicarbonate is faster than that producing sodium bicarbonate.

Similarly, a moderate quantity of calcium oxide (CaO) was found to be formed on the surface of calcium exposed to air for about five minutes. On comparing this pattern with that obtained in the magnesium experiment under similar conditions[1], it is apparent that the oxide film on calcium is much thicker than that on magnesium.

These results reveal the fact that the carbon dioxide in air can act on potassium or sodium within the limited period of about five minutes, but not on lithium or calcium; while oxygen and the moisture in air act on all metals here investigated.

Full details of these experiments will be published in the *Scientific Papers* of this Institute. The work has been conducted under the direction of Dr. Ichiro Iitaka.

Separation of Uranium Isotopes

The separation of the uranium isotopes is of interest because only one of the isotopes, ^{235}U, is believed to undergo fission when bombarded by slow neutrons. The best way to check this theory would be to change the relative particle density of ^{235}U and to see if that has any influence on the number of fissions caused by a certain number of neutrons. If the theory proves correct, one might be able to cause a nuclear chain reaction by concentrating ^{235}U and removing the other isotopes, which only catch neutrons without producing new ones.

To begin with, the most suitable method for concentrating ^{235}U seems to be the thermal-diffusion method of Clusius and Dickel[1] or Brewer and Bramley[2], this method being a universal one, applicable to all elements. Of course, other methods, specifically suitable for uranium, may be found later on. The thermal diffusion method can be used both for liquids and for gases, but it works extremely slowly when applied to liquids. It is much better to use gases. The only volatile compound of uranium is uranium fluoride (UF_6). The dimensions of a thermal-diffusion tube system, using this compound, can be calculated from the formulæ of Furry, Jones and Onsager[3]. We shall use the same notation as these authors.

The molecular weight of uranium fluoride being 352, the factor α is about $1 \cdot 5 \times 10^{-3}$. The temperature of the colder outer tube must be about $T_1 = 333°$ K. $= 60°$ C., if the apparatus is run at ordinary pressure, as uranium fluoride is a solid below 59° C. at a pressure of 760 mm. mercury. The temperature T_2 of the hot tube can be about $2T_1 = 666°$ K. $= 393°$ C., as experiments have been made with uranium fluoride at 440° C. without decomposition of the gas. Too high a temperature would increase the difficulties of getting materials resistant to uranium fluoride and the loss of energy caused by radiation of the hot tube. For the length of the tubes we take $2l = 10$ m.; for the outer diameter of the inner tube 4 cm. and for the pressure 1 atmosphere. The natural abundance of ^{235}U is 1/139, and if we demand a tenfold increase of the relative particle density of ^{235}U in the equilibrium state of discontinuous operation, we must put $A_d = 1{\cdot}49 \times 10^{-3}$ cm.$^{-1}$. For uranium fluoride no value has been measured for D, the coefficient of thermal diffusion, and η, the viscosity, but we may assume $D \sim 0{\cdot}05$ cm.^{2}/sec. and $1{\cdot}4\ \ \eta/\rho = D$ (ρ = density). This assumption gives us for $2w$, the distance between the tubes, $2w = 1{\cdot}34$ mm.

If the top reservoir contains 5 gm. uranium fluoride, the relaxation time would be 80 days. After this time, the concentration of ^{235}U would have increased to 6·7 times of its original value, or to about 4·8 per cent. If we remove the fluoride after this time from the top of the apparatus, we should get about 62·5 mgm./day of uranium fluoride, or 42·5 mgm./day of uranium, 4·8 per cent of the uranium removed being ^{235}U. In continuous operation we should get only 41·7 mgm./day of uranium fluoride or 28·3 mgm./day of uranium, if 4·8 per cent of the uranium removed be ^{235}U.

Thus a considerable quantity of uranium fluoride with the abundance of ^{235}U several times greater than its natural value can be produced by an apparatus which would not be too difficult to construct and to run. I began to construct such an apparatus together with B. Grabe, in August 1939, but the work had to be discontinued because of the political situation.

Radio Wave Reflections in the Troposphere

IN recent publications, Friend and Colwell[1,2] have reported the reflection of radio waves at vertical incidence from temperature inversions in the troposphere, and have estimated the reflection coefficient to be of the order of 10^{-3} at a frequency of 2398 kc./s. On the assumption that atmospheric reflections are due to discontinuities in water content, Piddington[3] has calculated the reflection coefficient to be not greater than 10^{-4}.

The reception of ultra-short wave signals at distances of the order of 100 km. is known to be correlated with the existence of atmospheric irregularities[4], and these signal strength measurements may be used to calculate the reflection coefficient for longer waves at vertical incidence. Since the air-mass boundary occurring at a temperature inversion must occupy a finite thickness, the effect of this diffuse boundary must be taken into account.

The propagation of electromagnetic waves in a stratified medium has received considerable attention in view of its application to optics and reflections from the ionosphere[5]. In the case of tropospheric reflections, where the variations in dielectric constant are very small, the calculation is much simplified and the method adopted by Darwin[6] and Hartree[7] of integrating the wavelets scattered by each part of the medium may be readily modified to give the required result. If the dielectric constant ε of the atmosphere is taken to be a continuous function of the height z only, and the diffuse boundary extends from z_1 to z_2, the reflection coefficient for radio waves of wave-length λ incident at an angle θ is

$$\rho\,(\lambda,\theta) = \left|\tfrac{1}{4}(\sec^2\theta - A)\int_{z_1}^{z_2}\frac{d\varepsilon}{dz}\cdot\exp\left(-\frac{i4\pi z\cos\theta}{\lambda}\right)\cdot dz\right|,$$

where A is 0 for horizontal polarization and 2 for vertical polarization. At normal incidence this is equivalent to the expression given by Försterling[8]. Whatever variation with height is assigned to ε, there is a simple relation between oblique and normal incidence, namely:

$$\frac{\rho\ (\lambda\,,\ \theta)}{\rho\ (\lambda\sec\theta,\,0)} = \sec^2\theta - A.$$

The measurements of Englund, Crawford and Mumford[4] on the propagation of 4·7 metre waves over a distance of 112 km. may by this relation be used to calculate the corresponding reflection coefficients for a wave-length of approximately 160 metres at vertical incidence. The result lies between 10^{-6} and 3×10^{-5}, the upper limit being in agreement with the experimental values of Appleton and Piddington[9] for random echoes from the troposphere.

It is interesting to compare the values of reflection coefficient for diffuse and sharp boundaries. If reasonable assumptions are made as to the height variation of ε, the reflection coefficient at normal incidence falls to half that for a sharp boundary when the transition layer is about one quarter wave-length thick. For a typical case of ultra-short wave transmission at grazing incidence, where θ differs from $\pi/2$ by about 0·03 radian, the corresponding thickness is about eight wave-lengths.

Blue Rocksalt

IN a letter in NATURE of February 17 under the above title, Dr. J. Newton Friend and John P. Allchin suggest that the blue colour of rocksalt may be derived from colloidal gold present in the sea-water from which the rocksalt has crystallized out, and give a content of 1 p.p.m. of gold as sufficient to produce a decided tint to a crystal.

From an oceanographer's viewpoint, it may be observed that this proportion of gold to sodium chloride would correspond to a gold content in the original sea-water of about 25 mgm./ton, whereas the highest gold content found by F. Haber and co-workers (in water from the East Greenland polar current) was 0·04 mgm./ton, the average value for the South Atlantic surface water being at least ten times less.

Rhythmical Impedance Changes in the Trout's Egg

MANY measurements have been made in recent years of the electrical impedance of cells such as those of nerve, Nitella and of marine eggs, and it has been found that such measurements yield valuable information as to cellular structure and reactivity.

Fertilized and unfertilized trout's eggs undergo rhythmical impedance changes when they have been in water for about six hours[1]. Further experiments show that this effect is not associated with the cytochrome system, as sodium nitride, carbon monoxide and lack of oxygen do not affect it. On the other hand, suitable concentrations of phenyl urethane reversibly abolish the effect. The action of the anæsthetic is shown in Fig. 1. The recovery part of the record has been omitted as it has no features of special interest.

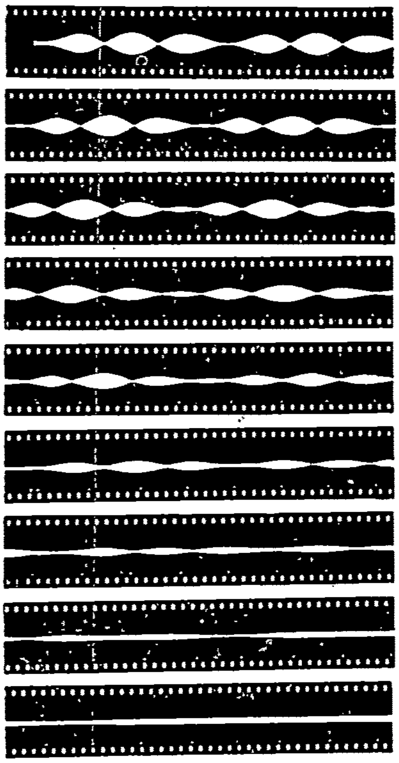

Fig. 1.

THE EFFECT OF PHENYL URETHANE ON THE IMPEDANCE CYCLE IN AN UNFERTILIZED TROUT EGG. THE ANÆSTHETIC WAS APPLIED AT THE BEGINNING OF THE RECORD. TIME-MARKER, MINUTES.

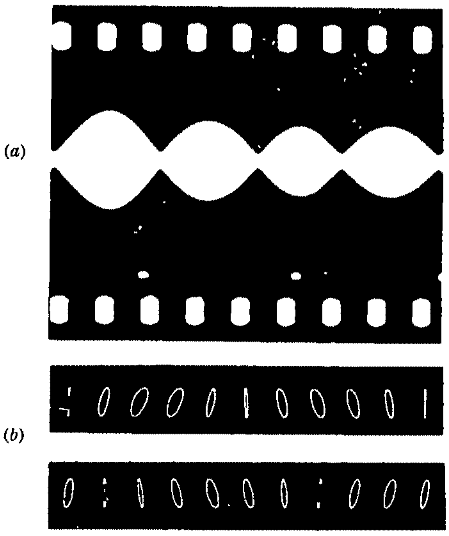

Fig. 2.

a, TWO COMPLETE IMPEDANCE CYCLES. TIME-MARKER, MINUTES.
b, SIMULTANEOUS RECORD OF THE RESISTANCE AND CAPACITANCE CHANGES IN THE EQUIVALENT CIRCUIT. THE ELLIPSES ARE 7·5 SEC. APART.

A change in impedance is due to a change in resistance and/or capacitance. (Inductances need not at present be considered in biological systems.) By using the 'ellipse' method of resolution[2], one can evaluate the resistive and capacitative components of the egg impedance cycle in the parallel circuit equivalent at a particular frequency to the trout egg in tap-water. This is shown in Fig. 2. Here, simultaneous moving film records of the impedance cycle, the resistive (R_p) and the capacitative (C_p) components are recorded. If R_p (as the angle of tilt of the ellipse) and C_p (as the minor ellipse axis) are plotted against time, the resultant curves are in phase every other cycle and approximately sinusoidal.

Fluorescence and Oxidation in Conjugated Ring Systems

THE study of the fluorescence of organic substances has shown that strong fluorescence is almost entirely confined to conjugated ring systems, which possess the highly mobile electrons. Theoretically, it is clear that a substance can only then exhibit fluorescence if the potential curves of the ground state and the excited state do *not* cross each other (or come very near to each other) so that the transformation of electronic excitation energy into heat cannot occur.

Thus the essential conditions for fluorescence are: (1) the excitation of the electron must not change appreciably the internuclear distance; (2) there must be no favoured position for the electron where it can be 'trapped' and thereby its kinetic energy transformed into potential energy.

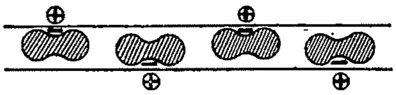
Consequently, only the more symmetrical conjugated systems or those which do not give rise to strongly ionic structures will show intense fluorescence.

The increase of the number of 'mobile' electrons, for example, in the series benzene → naphthalene → anthracene → . . . . → graphite, makes them behave increasingly like 'metallic' electrons as regards their optical and electrical behaviour.

We have found that this analogy to a metal can also be applied to some extent to the chemical structure and the reactivity of conjugated ring systems in general. It should be possible to prepare stable *positive ions* from the more 'metal-like' hydrocarbons by the action of oxidizing agents, and these positive ions should be capable of forming salt-like compounds. Various ionic compounds (bisulphate, perchlorate, etc.) have actually been prepared more recently from graphite by Hofmann[1] and collaborators by acting on it with an oxidizing agent in the presence of strong acids (sulphuric, perchloric). A certain number of hexagons in the layer planes loose an electron to form a monovalent positive (macro)-ion and this ion combines with HSO_4^- or ClO_4^- ion which goes between the layer planes of the graphite.

In view of the above-mentioned analogies with the metals, there can be no doubt that at least some of the peroxides of highly conjugated hydrocarbons, and in particular graphitic oxide, are essentially of ionic nature. The general formula of these compounds is most probably $[(\text{Hydrocarbon}+)O_2^-]$. They are sometimes formed in a thermal reaction as in the case of triphenyl methyl[2], giving $[(C_6H_5)_3C+.O_2^-]$. In the case of the diamagnetic hydrocarbons (for example, rubrene[3] or 3 : 10 dimethyl 1 : 2 benzanthracene[4], the peroxide is only formed under the influence of light, which decreases the ionization potential in the excited state and thus helps the formation of a positive ion.

The existence of O_2^- ion in peroxides like KO_2 has been shown by Pauling and Neuman[5] and its electronic structure has been discussed in detail[6]. Graphitic oxide should then be considered as a salt similar to the other graphite salts where the anion HSO_4^- or ClO_4^- is now replaced by O_2^- (or possibly partly by HO_2^-) (see diagram). This structure, of course, only refers to the '*active*' *oxygen* in graphitic oxide. The rest of the oxygen is present partly in the form of OH groups (possibly OH-ions) or as molecular water.



SCHEMATIC REPRESENTATION OF THE STRUCTURE OF GRAPHITIC OXIDE (SHADED PARTS REPRESENT O_2^- IONS BETWEEN THE LAYER PLANES OF THE GRAPHITE).

The ionic nature of graphitic oxide is also confirmed by the observed distance of layer planes, and by the fact that interplanar swelling can only be effected by *polar* solvents[1], a fact which was not understood previously.

The positive ions of graphite can be easily reduced[1] (reversibly) again to graphite, and this is also true for some of the hydrocarbon-peroxides which are decomposed by light or heat giving the unchanged ring systems.

Conjugated systems are of great biological interest and their biological significance seems to lie in the fact that they can undergo reversible oxidation, as has been made very probable in the case of chlorophyll[7]. The carcinogenic hydrocarbons also belong into the group of fluorescent conjugated ring systems[8] and it is quite possible that the oxido-reduction of these 'metal-like' hydrocarbon ions, namely,

$$(\text{Hydrocarbon}+)\underset{\text{oxidation}}{\overset{\text{reduction}}{\rightleftarrows}}(\text{Hydrocarbon}),$$

is an essential factor in causing the abnormal metabolism.

A full account will be published elsewhere.

Ionization of Calcium Phytate

IT has been pointed out by Bruce and Callow[1], and again recently by Harrison and Mellanby[2], that the rachitogenic property of cereals may be due to the formation of a sparingly soluble salt of phytic acid and calcium. In this laboratory, investigations on the chemical properties of this compound have shown that sodium phytate can only form an insoluble precipitate when an equivalent or an excess of calcium is added. Under such conditions the filtrates are clear and contain only a trace of phytic acid. When less than half the equivalent quantity of calcium is added, no precipitate is formed and the solution remains clear. *The calcium in the solution is not precipitated by the addition of phosphate or oxalate.* This indicates complex ion formation, and also that the degree of ionization of free calcium is extremely small. When the amount of calcium is between one half and one equivalent the solution is turbid and difficult to filter.

The magnesium ion reacts with sodium phytate in the same way. When a mixture of calcium and magnesium ions is added in excess of that required by the phytate, magnesium can take the place of the calcium in the precipitate to a certain extent.

[2] Harrison, D. C., and Mellanby, E., *Biochem. J.*, **33**, 1660 (1939).

WITH reference to the above letter, we should like to point out that we showed in a recent paper on phytic acid and the rickets-producing action of cereals[1], that the greater part of the calcium in a hydrochloric acid extract of oatmeal is, in fact, precipitated as phytate on bringing the solution to the neutral point, even though the total amount of calcium present is much less than equivalent to the phytic acid in the solution. Possibly the magnesium which is also present in the extract assists in the precipitation of calcium by forming an insoluble magnesium-calcium phytate instead of a soluble sodium-calcium double salt[2] which may be formed under the conditions described by Yang. Unfortunately, he does not state the hydrogen ion concentration under which his observations were made.

We found, too, that the filtrate from the neutralized oatmeal extract still contained a small amount of calcium in solution in spite of the presence of excess of phytic acid, and that addition of further amounts of calcium caused precipitation. We suggested that the residual soluble calcium was probably in an unionized form and therefore nutritionally unavailable. The observations of Yang appear to lend support to this suggestion, though as stated in our paper, we feel that there is not sufficient evidence to decide whether phytic acid exerts its rickets-producing action by actual precipitation of calcium or by lowering the ionization and diffusibility of calcium of the food. It seems possible that it may act in both ways, the depression of ionization being of relatively more importance at a faintly acid intestinal pH where precipitation of calcium would be less great.

Action of Œstrogens on the Female Genital Tract

IN an attempt to elucidate the mode of action of œstrogens on the female genital tract, we have conducted tests with cover-slip cultures of rat vagina and uterus.

Fragments of vagina from young albino females about three weeks old were explanted in the following media: (*a*) normal male rat serum; (*b*) normal male rat serum diluted with (i) 25 per cent of distilled water, or (ii) 25 per cent of an aqueous solution of diethylstilbœstrol containing 7·5 μgm. per ml.; (*c*) male rat serum ground up with a few crystals of œstradiol and filtered.

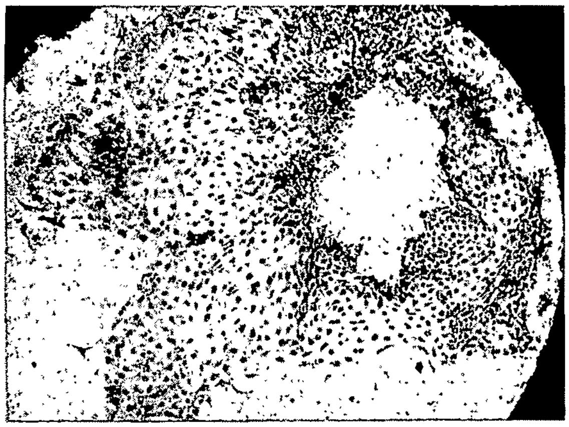

FIG. 1.

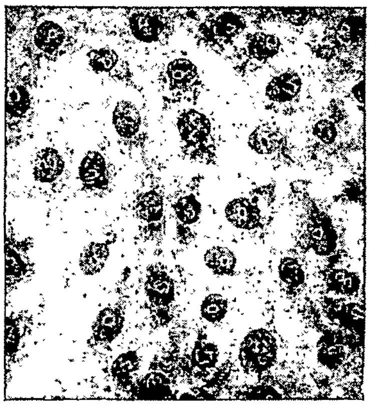

FIG. 2.

Six cultures were prepared with each type of medium. The explants became rounded after twenty-four hours. Afterwards some desquamation of the epithelium occurred, but there was little cellular outgrowth. After three and after four days, explants were fixed and sectioned. No histological difference was detectable between those incubated in the different media. There were very few mitoses in the epithelial cells, and no indication of active proliferation or cornification having occurred.

A further series of cultures was set up in a medium composed of equal parts of chick embryo extract, and a mixture of three parts of rat plasma to two parts of fowl plasma. Fragments of the uteri and vaginæ of five-day-old rats were explanted. After twenty-four hours incubation there were outgrowths of sheets of epithelial cells from most of the uterine explants, but the vaginal explants showed less growth. The cultures of each tissue were then divided into four sets of six cultures, *A*, *B*, *C* and *D*, exhibiting approximately equal growth from set to set. Different treatments were then given to the cultures of the four sets. *A* received a drop of arachis oil, *B* a drop of arachis oil containing 1·0 mgm. of œstradiol per ml., *C* a drop of distilled water, and *D* a drop of distilled water containing *ca.* 50 μgm. of colloidal œstradiol per ml.

Cultures were fixed 24, 48, and 96 hours after treatment for cytological examination. However, the hormones had no demonstrable action, and there was no difference between the various sets of the same tissue.

The type of culture with which we have been working is illustrated in Fig. 1, the explant having been removed after fixation. This represents four days growth *in vitro*, and two days treatment with a drop of distilled water. Fig. 2 shows at a higher magnification a part of a similar culture after treatment with colloidal œstradiol for two days. Both of the cultures were of uterine fragments. We are satisfied that the cultures were brought in contact with more than sufficient œstrogen to cause the changes characteristic of œstrogenic stimulation *in vivo*, and in view of the healthy state of the cultures, it appears improbable that œstrogens act directly on the vaginal or uterine epithelia.

While this work was in progress, Hechter, Lev and Soskin[1], following the work of Reynolds[2] and Pompen[3], showed that vaginal cornification in the mouse produced by œstradiol benzoate may be inhibited by atropine, and that cornification follows the administration of yohimbine. The uterine response was only partially inhibited by atropine. Hechter and his co-workers believe that the vaginal response, and part of the uterine response to œstrogens, is dependent upon hyperæmia, a conclusion which is complementary to our own, since we found no indication of a direct action of œstrogens upon the epithelial cells.

'Coupling' of Phosphorylation with Oxidation of Pyruvic Acid in Brain Tissue

Lipmann[1] found that, although adenylic acid does not influence the rate of oxidative decarboxylation of pyruvic acid by preparations of lactic acid bacteria, it is phosphorylated to adenosine-polyphosphate. With brain dispersions it has been shown in this laboratory[2] that oxidation of pyruvate requires the presence of both inorganic phosphate[3] and adenine nucleotide (adenylic acid, adenosine-triphosphate). These observations suggested that a cycle of phosphorylation is involved in the enzymatic oxidation of pyruvate.

Brain preparations contain an active adenosine-triphosphatase[2] and, in the presence of adenylic acid (without or with creatine), only small amounts of adenosine-polyphosphate (or creatine phosphate) accumulate. However, that oxidation of pyruvate in brain tissue is accompanied by an intensive esterification of phosphate has now been shown by using hexosemonophosphate as an acceptor for the labile phosphorus groups of adenosine-triphosphate[4]. When hexosemonophosphate is added to a dialysed brain dispersion containing phosphate, Mg^{++}[5], adenylic acid, fumarate[2], pyruvate, and NaF (phosphorylation also occurs in the absence of NaF), and the mixture is incubated aerobically, inorganic phosphorus is taken up (Table 1) and an equivalent amount of hexosemonophosphate is converted into hexosediphosphate. As much as 0·8 mgm. hexosemonophosphate phosphorus can thus be phosphorylated in 35 min. at 38°. The hydrolysis curve (in *N* HCl at 100°) of the resulting ester is that of hexosediphosphate which, under these conditions, does not seem to react further significantly; this is confirmed by the failure to detect formation of phosphoglyceric acid by Rapoport's[6] method. No esterification of phosphate occurs in the absence of pyruvate plus fumarate and very little in the absence of adenylic acid. Thus oxidation of pyruvate is accompanied by phosphorylation of adenylic acid to adenosine-polyphosphate which, in presence of hexosemonophosphate, transfers its labile phosphorus to the latter instead of being hydrolysed by the adenenosine-triphosphatase. Table 2 shows that, in 30 min., approximately 2 atoms phosphorus are esterified for 1 mol. pyruvate disappearing and 1 mol. oxygen taken up.

Table 1.

1·5 ml. dispersion from pigeon brain (dialysed 2·5 hours) to 2·2 ml. with phosphate buffer *p*H 7·3 (0·05 *M*) Mg^{++} (0·2 mgm.), adenylic acid (0·0007 *M*), Na fumarate (0·005 *M*), Na pyruvate (0·013 *M*) and NaF (0·04 *M*). Air, 38°.

(O_2 uptake = difference between complete samples and samples containing no pyruvate + fumarate).

Time (min.)	O_2 uptake (μ 1)	Pyruvic acid (mgm.)	Inorg. Phosphorus (mgm.)
0	—	2·17	1·42
5	48	1·62	1·13
10	96	1·51	1·00
20	143	1·34	0·92
30	190	1·24	0·83

Table 2.

Time (min.)	O_2 uptake		Pyruvic acid disappeared		Phosphorus esterified	
	μ 1	μ mol.	mgm.	μ mol.	mgm.	μ atoms
30	190	8·5	0·93	10·5	0·59	19·0

The necessity of inorganic phosphate and adenine nucleotide for the oxidative breakdown of pyruvate in brain is thus explained. The recent work of Warburg and Christian[7], by which the mechanism of enzymatic oxidation of triosephosphate and the true nature of the 'coupled' esterification of phosphate are made clear, will throw much light upon the undoubtedly similar mechanism of pyruvate oxidation.

I am indebted to the Nuffield Trustees and the Rockefeller Foundation for grants in aid of this work.

Influence of Spermathecal Stimulation on the Physiological Activities of *Anopheles subpictus*

The introduction of spermatozoa into the spermatheca is not known to influence the physiological activities of a mosquito or of any other insect except that it serve [illegible]he purpose of fertilization of the ovum. That it h [illegible] arked action on egg formation in *Anoph* [illegible] has now been demonstrated.

W [illegible] ating of *A. stephensi* and *A.* [illegible] in ordinary feeding cages ir [illegible] do not pair under s [illegible] lso been noted feed to the same extent as in Nature. While a blood feed will lead to egg formation in virgin *A. stephensi* and *A. annularis*, it fails to do so in virgin *A. subpictus*, even when this mosquito has been allowed to feed to repletion on man, goat, or cattle, and evidence of follicular stimulation is the only noticeable change. This led Christophers[1] to abandon his observations on egg development in *A. subpictus* in the laboratory.

The presence of two distinct phases in the egg formation in *Aedes aegypti*, one stimulation of the follicle and the other formation of the ovum, was tentatively suggested by me[2]. The stage of follicular stimulation can be clearly demonstrated in *A. subpictus*, and is characterized by the appearance of very light peppery granules scattered irregularly. These are distinct from yolk granules, which are much coarser and are deposited in a much more compact manner. Distinction between these two stages in *A. annularis* is not possible unless the latter are allowed to ingest a very small quantity of blood, as otherwise the second phase overlaps the first.

It has also been observed in *A. subpictus* caught in Nature that ingestion of a large quantity of blood and yolk formation are solely dependent on the presence of sperms in the theca.

While reception of blood into the stomach is sufficient to cause stimulation of the follicles and yolk formation in virgin *A. annularis*, and only the former change in virgin *A. subpictus*, the introduction of sperms into the theca in the latter species can alone lead to yolk formation. The specific substance of the blood which is concerned with yolk formation in *A. subpictus* is intimately associated with the stimulation of the theca, and it is presumed a specific hormone is thereby produced.

Any suggestion that the failure of laboratory-fed *A. subpictus* to produce yolk owing to the ingestion of a smaller quantity of blood than the minimum amount necessary for egg production is untenable on account of the constant association between yolk formation and the presence of sperms in the theca, and also the reverse phenomenon noticed in mosquitoes caught in Nature[2]. Besides, the amount of blood ingested by *A. subpictus* in the laboratory does not seem to be insufficient for egg production.

Collections of the mosquitoes, *A. annularis* and *A. subpictus*, were made from the salt-lake area adjacent to Calcutta, and dissections were performed from day to day. Nearly five hundred specimens of each species were dissected.

The above conclusions have been arrived at from observations made during the winter months.

Photodynamic Hæmoly [illegible] 4-Benzpy [illegible]

IN a recent com [illegible] d
the photodyn [illegible] s
[illegible]
closely with Wolman's. But we varied and further extended the experiments in order to try to see how benzpyrene sensitizes red corpuscles. We have carried out the following investigations.

(1) Colloid solutions of benzpyrene in normal saline were made up in a series of dilutions from 1 in 10,000 to 1 in 100 million. Washed human red corpuscles were added to these and the mixtures kept in the dark for three hours. Some were then put in sunlight and controls kept in the dark. After 45 minutes exposure the red corpuscles in the 1 in 10,000, 1 in 100,000, and 1 in 1 million solutions showed approximately the same amount of partial hæmolysis. This was complete in two hours, by which time a partial hæmolysis was present in the 1 in 10 million solution. There was no hæmolysis in the 1 in 100 million solution in the light and none in the controls kept in the dark.

(2) Colloid benzpyrene solutions were given a prolonged exposure to light. Red corpuscles were then added and the mixtures kept in the dark. No hæmolysis resulted.

(3) Suspensions of red corpuscles in benzpyrene colloid were left in the dark for various times and the corpuscles then washed free from benzpyrene. After this they were given a long exposure to light. Corpuscles which had been in contact with the hydrocarbon for five minutes showed a trace of hæmolysis, those in contact for one hour showed moderate hæmolysis, and corpuscles which had been in contact with the benzpyrene for three hours showed complete hæmolysis, in 45 minutes exposure to sunlight. The strength of the colloid was 1 in 100,000.

(4) Samples of red corpuscle suspensions in benzpyrene colloid (1 in 250,000) kept for 2½ hours in the dark at various temperatures were washed and exposed to light. Those which had been kept in contact with the benzpyrene at 0° C. showed only slight hæmolysis after prolonged exposure to a mercury vapour lamp. Red corpuscles which had been in contact at 37° C. showed a comparatively rapid hæmolysis under the lamp.

Thus, using red corpuscles, the photodynamic potency of benzpyrene is roughly the same in dilutions of 1 in 10,000 to 1 in 1 million. Paramecia gave a similar result (Doniach[2]). Washing red corpuscles which have been suspended in benzpyrene does not get rid of their sensitivity to light. This sensitivity is enhanced by prolonged contact with the hydrocarbon and by raising the temperature at which the corpuscles are suspended in the colloid. These results indicate that the benzpyrene must enter into the red corpuscles before a photodynamic action can start. If it were a matter of simple adsorption on to their surface one would have expected contact at 0° C. to have been more effective than contact at 37° C. The enhancement at higher temperature is likely to be due to an increased solubility of the benzpyrene in water, an assumption in accord with recent results of other experiments in this laboratory.

Acetolysis of Carrageen Mucilage

IN a series of papers published between 1921 and 1929, Haas and his collaborators[1] showed that in the mucilage of carrageen moss (*Chondrus crispus*) there are two main constituents one of which can be extracted from the seaweed by cold water, the other only by hot water. They further showed that both constituents are ethereal sulphates of polymeric carbohydrates, occurring chiefly in the form of their calcium salts; but all their attempts to isolate the polymeric carbohydrates by hydrolysis led only to the production of simple hexoses. Galactose and fructose were easily recognized by them among the products of hydrolysis.

We have now acetylated the mucilage by treatment with acetic acid and acetic anhydride under the catalytic action of sulphur dioxide and chlorine, and on removal of the acetyl groups from the product we have obtained two polymeric carbohydrates each containing about 0·1 per cent of ash and giving analyses which agree well with the formula $(C_6H_{10}O_5)_n$. One of these bodies is soluble only in hot water and gives with iodine a wine-red colour similar to that given by glycogen, while the other is soluble in cold water and gives no characteristic colour with iodine. After hydrolysis neither compound gives glucosazone nor does either give the Seliwanoff reaction for fructose; the latter reaction is, however, given by the alcoholic liquid from which the polymeric carbohydrates have separated on deacetylation. From both polymers the characteristic α-methylphenylhydrazone of galactose was prepared and both gave mucic acid on oxidation with nitric acid.

Both polymeric carbohydrates appear to be galactans. In physical properties they resemble the body isolated by Hassid[2] from *Irideæ Laminarioides* more than that obtained by Percival and Sym[3] from agar.

Further investigation of these products is in progress, and detailed results will be published elsewhere.

Points from Foregoing Letters

A NEW formula connecting tensile strength with latent heat of melting and Poisson's elastic constant has been developed by R. Fürth and found to be in good agreement with experiment.

Electron diffraction studies show, according to S. Yamaguchi, that when potassium and sodium are exposed to air they are attacked within five minutes by carbon dioxide, but lithium and calcium are not attacked. Oxygen and moisture in the air attack all four metals.

W. Krasny-Ergen describes a suggested apparatus for the separation of uranium 235.

L. G. Stoodley has shown how measurements of the signal strengths of ultra-short waves reflected at grazing incidence at a diffuse boundary in the troposphere may be used to calculate the reflection coefficient for longer waves at vertical incidence. The results are in agreement with the experimental values of Appleton and Piddington.

Records of the rhythmical impedance changes undergone by an unfertilized trout egg are submitted by Lord Rothschild. From resistance and capacitance changes in an equivalent circuit, it is found that resistance and capacitative components plotted against time give curves which are in phase every other cycle and approximately sinusoidal.

J. Weiss states that the fluorescence of conjugated ring systems is essentially due to the presence of the 'mobile' electrons, which are also responsible for the chemical behaviour of these substances. The structures of some related hydrocarbon-peroxides and of graphitic oxide are deduced, and a possible mechanism for the action of carcinogenic hydrocarbons is suggested.

E. F. Yang finds that when sodium phytate is present in excess, calcium is not precipitated as the phytate but remains in solution in an un-ionized form which is not precipitated by addition of oxalate or phosphate. D. C. Harrison and Sir Edward Mellanby find that this non-precipitation of calcium as phytate does not hold for oatmeal extracts. Their experiments indicate that the rickets-producing action of cereals is due to phytic acid, which interferes with calcium absorption from the intestine. They suggest that the cereal phytic acid may exert a rachitogenic action partly by precipitating calcium in the intestine and partly by rendering the calcium un-ionized and thus impeding its absorption.

The application of œstrogens by C. W. Emmens and R. J. Ludford to tissue cultures of vagina and uterus failed to induce either proliferation or cornification of the epithelial cells. Hence it is concluded that the characteristic histological changes following œstrogenic stimulation *in vivo* are not the result of a direct action of the hormones on the epithelial cells.

S. Ochoa finds that oxidation of pyruvic acid in brain preparations, in the presence of phosphate, adenylic acid, and hexosemonophosphate, is accompanied by conversion of the monoester into hexosediphosphate with an equivalent uptake of inorganic phosphorus. This 'coupling' explains why both inorganic phosphate and adenylic acid are necessary for the oxidation of pyruvate in brain.

I. Doniach and J. C. Mottram report that human red corpuscles were sensitized to light with 3 : 4-benzpyrene. The hydrocarbon was active down to a dilution of 1 in 10 million. Washing red corpuscles which had been suspended in benzpyrene colloid did not rid them of their sensitivity to light. The photodynamic reaction was enhanced both by prolonged contact in the dark of the corpuscles with the benzpyrene and by raising the temperature at which contact was made.

By acetolysis of carrageen mucilage, T. Dillon and P. O'Colla have obtained two polymeric carbohydrates, one soluble in cold water and the other soluble in hot water and giving a characteristic colour with iodine. Both appear to be galactans.

RESEARCH ITEMS

Fertility Cults in East and West

A POSSIBLE link between the Mediterranean and adjacent regions of the ancient world and Japan in the symbolism of the cowrie as a fertility emblem is discussed by Kurt Singer (*Man* of April 1940). While Elliot Smith's theory of the cowrie as a "life-giver" and closely associated with parturition and other fecundity cults has been accepted, for example, by J. Gunnar Andersson, as a working hypothesis making it possible to range under a single point of view all the varying uses of the cowrie, a difficulty is that no Neolithic figurine of the Astarte type shows any recollection of the cowrie talisman. The Western evidence in figurine and cult observances is suggestive rather than conclusive, but a Neolithic (*Jōmon*) figurine from north-eastern Japan is unique in showing not only unusually strongly accented breasts, but also what appears to be a monstrous vulva but is probably the giant image of a cowrie shell hanging from a cord attached to the neck-band. The ritual use of powdered shell and water for various ceremonies may also be thought to confer life and force by administering a simulacrum of mother's milk produced from a simulacrum of the womb. Two masks recall the traditions about Baubo-Iambe and Demeter. They formed the central part of the autumn procession at the festival of the Gongoro Jinja in Kamakura, and were worn one by a woman showing signs of distraction and the other by a woman obviously with child who addressed ribald remarks to male onlookers. The procession closed with men carrying poles, recalling phallic symbols. Arguments and parallels may be cited in support of the suggested resemblance to Demeter and Baubo.

Stomatopoda from the John Murray Expedition

Two memoirs on the Stomatopoda have recently appeared (John Murray Expedition, Scientific Reports 6, No. 3, by B. Chopra, No. 6, by G. E. H. Foxon. British Museum (Natural History), 1939). The collection of Stomatopods is small but of interest. Some are of large size, more than 300 mm. in length. Sixteen species and varieties are recorded, one species of Squilla and one of Lysiosquilla being new. The variation in the raptorial teeth in *Squilla investigatoris* is remarkable; also the variation of the relation of rostrum to eyes in *Lysiosquilla multifasciata*. There are many varieties of *Gonodactylus chiagra*, some of which are regarded as distinct species. A small one was dredged at the unusual depth of 1,300 m. Fragments of *Squilla investigatoris* were also dredged at this depth, but it is, of course, not certain that the species was actually living there—a record depth for any Stomatopod. It is difficult to place the new species *Lysiosquilla sewelli*, which combines characters of this genus with those of several others. In his work on the larvæ, Foxon has modified his former classification (1932, Great Barrier Reef Report) which has been criticized by Guerney (*Proc. Zool. Soc.*; 1937) who regards the classification of Giesbrecht as the more natural one in which the two fundamental types of larva, antizoea and pseudozoea are separated. The revised key gives two main groups, the first containing Coronida and Lysiosquilla (antizoea larva), the second containing all the others. In the second group Squilla and Pseudosquilla are placed close together, in agreement with the adult classification of Kemp, and Odontodactyla and Gonodactylus which have early larvæ very similar to Pseudosquilla and different from Squilla, in another section. It is shown that Squilla larvæ occurred everywhere, but in great numbers near the coast. Pseudosquilla larvæ are likely to be found near land, and Lysiosquilla larvæ are the most likely to be found farthest from land.

Turbellaria from Bermuda and the Sargassum

L. H. HYMAN has recently described a valuable collection of Acoel and Polyclad Turbellaria derived from material collected by herself, by Dr. Wheeler and by Dr. Verrill in Bermuda, and also several Sargassum collections from the Bingham Oceanographic expeditions to the western and central North Atlantic, the Gulf of Mexico and the Caribbean (*Bull. Bingham Oceanograph. Coll.*, Peabody Museum of Natural History, Yale University, 7, Art. 1; 1939). Nine plates of clear drawings illustrate this paper, in which there are two new species of Acoela, eleven known and two new species of Polycladida, and one new variety of Polyclad. Many of these were collected on the shore at Bermuda, but there are also species from the floating Sargassum weed which is a fruitful hunting ground for these worms. The Polyclads are chiefly species originally described by Verrill in 1900 and 1901 and these are now assigned to their proper genera with details of their sexual anatomy. Use has been made of colour drawings made from live specimens by Dr. Wheeler, director of the Bermuda Biological Station, which makes the descriptions doubly valuable; the whole monograph forms a useful addition to the rapidly growing series of writings on the Bermudan fauna.

Identification of Plants of Tanganyika Territory

"A FIELD Key to the Savanna Genera and Species of Trees, Shrubs and Climbing Plants of Tanganyika Territory" by the late B. D. Burtt (published by the Tsetse Research Department) should prove extremely valuable to workers in this part of Africa, where it is difficult to get plants named locally, especially as the collections are housed in European herbaria. Many of the workers in Tanganyika are attached to technical departments, and the key will have added value from the fact that its use does not require a preliminary botanical training, so that anyone dealing with plants as indicators of soil conditions, timber trees or plants with poisonous or useful properties will be able to record his observations in the concrete form of a correct botanical name. Though primarily concerned with plants of Tanganyika, the savannah plants are very similar in the neighbouring parts of Northern Rhodesia Nyasaland, Uganda and Kenya, so that, with reservations, the key may be applicable to the savannahs of these districts or serve as a basis for a similar key. It is much to be regretted that Mr Burtt's death has interrupted this work, of which he had outstanding knowledge, but it is to be hoped that in time the key to the genera will be supplemented by a key to the species as originally intended.

A Fossil Link between North America and Asia

A MAIL report from Science Service and the Smithsonian Institution announces the clarification of a problem which has long puzzled American geologists. Large numbers of fossil leaves which somewhat resembled the foliage of living poplars have been collected between Greenland and south-western Tennessee, for the past seventy years. Roland W. Brown suggests that the leaves are similar to those of a present-day Japanese tree, the katsura. He further argues that if leaves were fossilized through being blown into mud, it ought to be possible to find also the fossil seeds. Katsura seeds have sickle-shaped wings and are wind-blown. Dr. Brown ultimately found a few of them fossilized in the localities where the fossil leaves occurred. A study of variation in leaf form of the present-day tree paralleled the various types of fossil foliage. This brilliant piece of palæontological investigation adds yet another to the fossil links, such as those of the horse, which bind North America and Asia.

Genetics of the Garden Pea

GENETICAL experiments with the edible pea, *Pisum sativum*, have been carried on since the time of Mendel. Nevertheless, the linkage relationships of even the well-known characters, round-wrinkled seeds or yellow-green cotyledons, are insufficiently known. C. Pellew (*J. Genetics*, 39, 363–390; 1940) has published some of her extensive linkage data. She shows how reciprocal translocations and trisomics enable us to identify the chromosomes and positions on the chromosomes where a particular gene is placed. The *K* reciprocal translocation of Hammerlund has been used for the present report. The genes, *A*, *I*, *Gp*, *Fs*, *R*, and *Bt* have cross-over percentages of 1, 1, 1, 20, 40, and 40, respectively, with the point of interchange. In normal lines *A-L* has 12 per cent crossing-over, *R-Bt* 30 per cent, and *Fs-Sp* about 42 per cent. Between these pairs of genes independence is shown in normal lines; but experiments with several translocations indicate that *A*, *L*, *R*, and *Bt* are all on chromosome 1. *Fs* and *G-p* are on chromosome 2, which with chromosome 1 took part in the *K* reciprocal translocation. The author also shows that competition and possibly elimination of certain types take place in the male gametophyte and in the young sporophyte.

Oxygen Isotopes in Rocks and Ores

A STUDY of Grenville marble, Niagara dolomite and Pennsylvania limestone and shells, all carbonates of widely different ages, made by M. Dole and R. L. Slobod (*J. Amer. Chem. Soc.*, 62, 471; 1940), reveals no significant difference in the ratio of the oxygen isotopes ^{16}O and ^{18}O as a function of the age of the rocks. The oxygen in iron ores of the Keewatin and Middle Huronian ages does not differ significantly in isotopic composition from the oxygen in normal water; the slight excess density observed in experiments on the oolitic and fossil type of Silurian ores is probably due to the presence of carbonates in the ores. The oxygen of Grenville marble when liberated as carbon dioxide and reduced with hydrogen gives water 9·2 p.p.m. heavier than normal, but when the carbon dioxide is driven out of the rock by heating, the resulting water is only 7·9 p.p.m. heavier. The difference is attributed to the isotopic fractionation which occurs when the carbonate ion is decomposed by acid. The authors discuss the question as to whether the isotope ratio corresponds with sea-water or rain-water.

X-Ray Diffraction of Liquid and Plastic Sulphur

THE anomalous behaviour of liquid sulphur in respect of viscosity, specific gravity, surface tension, thermal expansion, and specific heat at just above 150° has invited a study of the structure of liquid sulphur at different temperatures. Various workers have attempted to explain these anomalies on the basis of X-ray diffraction patterns, but recorded data are not consistent. In a recent publication (*J. Chem. Phys.*, 8, 29; 1940) Gingrich has attempted to clarify the position. He obtained and compared the X-ray diffraction patterns of liquid sulphur at eight temperatures between 124° and 340° and, in addition, that of plastic sulphur at room temperature. The intensity curve, as a function of $(\sin \theta)/\lambda$, for plastic sulphur is typical of an amorphous substance and shows three peaks. Those for liquid sulphur, corrected for absorption, polarization, and incoherent radiation, at 124°, 166°, 175°, 225°, and 340° show a main peak with two plateaux. The position of this peak shifts irregularly with temperature. Thus from 124° to 157° the value of $(\sin \theta)/\lambda$ decreases slightly, from 157° to 166° it gives a large decrease, and from 166° to 340° it decreases gradually. Atomic distribution curves show that (i) the first concentration of sulphur atoms in plastic sulphur is at 2·08 A. with two nearest neighbours, and (ii) 1·7 nearest neighbours are found at an average distance of 2·07 A. in liquid sulphur at all temperatures. (i) does not yield enough information to distinguish between closed rings of sulphur atoms and long coiled chains in plastic sulphur; and (ii) indicates that in liquid sulphur most atoms (about 70 per cent) still have two permanent neighbours which are covalently linked at the same distance as in the S_8 molecule, and about 30 per cent have one nearest neighbour.

The Mohammedan Calendar and the New Moon

J. H. REYNOLDS has discussed in a paper entitled "The Mohammedan Calendar and the First Visibility of the New Moon in Egypt" (*Occas. Notes Roy. Astro. Soc.*, No. 7; 1939) the months of the fast of Ramadan and the feast of Bairam, which commence when the thin crescent of the new moon is first visible after sunset. At the Helwân Observatory, two assistants are delegated to report both the beginning and ending of the month of the Ramadan fast, but sometimes a village sheikh in Upper Egypt or the Delta sends a wire to the Quadi's court announcing his discovery of the crescent. Occasionally the date of the alleged observation is known at the Observatory to be impossibly early. Reynolds applies J. K. Fotheringham's table (*Mon. Not.*, 70, 527; 1910), which shows the minimum true altitude at sunset or sunrise for the moon to be visible for true differences between the azimuths of the sun and moon, the latter ranging from 0° to 23°. While Fotheringham claimed that the table is independent of the latitude differences, Reynolds does not accept this view, and expresses the opinion that the table is probably inapplicable for latitudes of 50° and above. He suggests that the point would be worth verifying by observation, because of the importance of such factors as refraction and transparency of the atmosphere near the horizon.

ELECTRIC CABLES AND FIRE RISKS

MR. S. W. MELSOM, of the Cable Makers' Association, read a paper on March 13 on recent developments and investigations on electric cables and fire risks, before the Transmission Section of the Institution of Electrical Engineers.

During the last four years there has been general concentration on the problem of fire risks in electrical installations and on the precautions necessary to eliminate them. These problems, which apply to ships, power stations and mines, are probably mostly due to the immense spread of the use of electrical energy and the enormously increased size of the power units and of the distribution units and the distribution systems. As a result of the various inquiries that have been held, the encouraging news has emerged that nowadays the fire risk due to faulty cables is exceedingly small, so small, in fact, that it may almost be ignored, and that, as regards cables, the real precautions to be taken are in respect of the spread of extraneous fire along the cable.

So far as ships are concerned, shipping records justly direct attention to the excellent record of British shipping in this respect. Regarding power stations, the report of the Electricity Commissioners does not ask for any special protection from fires arising within cables, and as for mines, all the evidence of fires in mines has exonerated cables. However satisfactory the general volume of proof may be, it will be obvious that the cable-making industry was bound to make all possible investigations and, in particular, to help in the solution of the problem of resisting the spread of an extraneous fire along a cable run.

The author said that a great deal of work has recently been done on the fireproofing of mains cables in power stations, generally with the view of protecting them from breakdown due to adjacent cables, more particularly in the manholes which are part of the large duct systems prevalent in the United States. It was not until 1937 that the subject was given serious consideration in Great Britain. The committee set up by the Electricity Commissioners as a result of painful experience worked energetically at the problem, and we are deeply indebted to this committee for its clarification of the problem and for the resultant proper provision for protection against fire.

It may be assumed from the published recommendations of the Commission that, so far as cables are concerned, the main problems to be faced arise from extraneous fires mainly due to flowing burning oil in a station or a substation. The recommendations of the Commissioners were made after full consultation with the industry, and with them the cable-makers are in full agreement.

It may be useful to discuss the manner of giving effect to these recommendations, and the effect that the protection may have on the performance of the cables under normal operating conditions. The essential requirement for the fireproofing of lead-sheathed paper-impregnated cables is that the fireproofing should be sufficiently heat-resisting fully to protect the cable, of sufficiently low thermal conductivity so as not to decrease unduly the current rating of the cable, and that either its composition is such that it does not set up corrosion of the lead sheath or, alternatively, that it is provided with protection against such corrosion.

A combination of all these properties was not easy to find, and a good deal of investigation was required before the best materials were found. Also in some cases the use of the best method was not possible on systems already installed, and alternative methods had to be sought. Dealing with the question of cables emerging from the floor and going upwards to connect to switchgear, etc., or to other cables run in the vicinity of such gear, etc., the method selected for new installations and for existing installations where space was available was to use moulded asbestos supplied by the makers in the form of split-tubes which could be clamped around the exposed length of the cable. Apart from the ease of fitting and the comparatively pleasing finish of the work, this material represents the nearest approach to the ideal characteristics mentioned above. Magnesia has probably a higher degree of resistance to fire than the asbestos mouldings, but the thermal resistivity of the material is so high that the current rating of the cable would be greatly diminished.

The thermal resistivity of moulded asbestos is of the order of 700 thermal ohms, a value which with the thickness of material used would normally decrease the current rating of the cables by about 20 per cent. Against this, however, may be offset the normal increase of rating due to the fact that the cables to the ground are probably grouped, whereas when they are taken to switchgear they are separated apart a distance sufficient to free them from 'proximity heating'. This generalization, however, must not be carried too far, since if the cables in the run are separated throughout and operated at or near their maximum current, the asbestos-covered section would reduce the permissible current to an extent which would require serious consideration.

The fire-resisting properties of the moulded asbestos material appear to be extremely good. From figures quoted by the makers, the white asbestos material only begins to suffer damage when subjected to a temperature of 2,500° F., and the asbestos compound can withstand much higher temperatures for short periods. Tests carried out by the E.R.A. on cables protected by moulded asbestos exposed to a serious oil fire showed that, while parts of the burning enclosure reached a temperature of about 1,100° F., the highest recorded temperature on the protected cable sheath was 176° F. More severe tests of the same material used as a protective covering for steel girders showed that after a period of more than four hours exposure, during which the ambient temperature rose to 2,100° F., the temperature of the protected ironwork was only 850° F. It should be noted that the material is somewhat alkaline and that, to ensure protection against corrosion, the lead sheath of the cable should first be protected with a layer of bitumen paint and wrapped with one layer of bituminized tape.

For existing installations in which the conditions of erection are such as not to allow the use of moulded asbestos, a very good degree of fire resistance can be ensured by stripping off all the existing protective wrappings to the armour (or lead as the case may be), painting the cable with bitumen paint, wrapping with a layer of bituminized tape and then applying two layers of asbestos tape with a sensible overlap. The asbestos should be freely painted with silica paint.

For a number of years the research staffs of the associated firms of cable makers have been attempting to produce fire-resisting or self-extinguishing rubber compounds, and a fair degree of success has been obtained in imparting these properties to rubber. The fundamental difficulty has been that raw rubber is not self-extinguishing when once ignited, and the other materials which it is necessary to incorporate in the 'mix' to overcome the lack of self-extinguishing properties greatly modify its other desirable properties.

A new synthetic material has been discovered which belongs to the same general chemical group as rubber. This material in its raw state is very similar in its physical properties to raw rubber. It is converted into a suitable 'mix'. As, however, the material is fire-resisting, it is not necessary to obtain the fire resistance at the expense of other properties. Extensive tests have shown that this synthetic material is more resistant than rubber to deleterious influences.

Fires which have occurred in coal mines during recent years with deplorable loss of life raised the question in some minds as to how far electrical cables have been responsible for either initiating a fire or conveying an existing fire from one part of a mine to another. At the instigation of Mr. Horsley, electrical inspector of mines, the cable makers agreed to carry out experiments with the view of obtaining data which would answer certain specific questions. It was found that the application of a hot external flame for about 15 seconds was necessary to ignite the compound on the wrappings of a standard C.M.A. cable ; hence it does not seem probable that such wrappings around the cable would be ignited as the result of a transient flame such as would arise, for example, from an explosion of fire damp. The experiments also showed that the armour wires practically completely protected the inside of the cable. The cable makers have to be congratulated on the way they have co-operated in very expensive researches for their mutual benefit.

NEW INTERNATIONAL COMMISSION OF SNOW AND GLACIERS

BY F. E. MATTHES

AT the Seventh Assembly of the International Union of Geodesy and Geophysics, which was held in Washington last September, the International Association of Scientific Hydrology, one of the component units of the Union, effected the consolidation of two of its own commissions—the Commission of Snow and the Commission of Glaciers. The action was taken after a preliminary poll of the membership of the two commissions had shown an overwhelming majority in favour of the consolidation. Moreover, the presidents of both commissions, Prof. J. E. Church, of the University of Nevada, U.S.A. (snow), and Mr. J. M. Wordie, of St. John's College, Cambridge, Britain (glaciers), had strongly recommended it.

Prof. Church was designated acting president of the new Commission of Snow and Glaciers, to serve in that capacity until international relations will permit the holding of a formal election of officers. Like all other sections of the International Union of Geodesy and Geophysics, the Association of Hydrology has deferred election of officers for the present triennial period, in view of the sparse attendance of European delegates at the Washington assembly, due to war conditions.

The new Commission of Snow and Glaciers aims at taking into its purview all research relating to snow and ice in their varied forms. It might appropriately have been named Commission of Snow and Ice, but it preferred to adopt the name Commission of Snow and Glaciers in deference to the former Commission of Glaciers, which is by far the older of the two bodies that are now consolidated, and which, indeed, was in existence long before the Association of Hydrology was formed.

The original Commission Internationale des Glaciers had its inception in 1894, at the International Geological Congress at Zurich. It was charged, broadly, with the task of studying existing glaciers throughout the world ; but actually its efforts have been concentrated on securing statistics of the secular variations—advance and recession—of glaciers in response to climatic fluctuations. Inasmuch as this task requires the making of annual measurements on large numbers of glaciers in different countries, with the aid of co-operating agencies, governmental, scientific, and other, it has inevitably grown into a vast enterprise. The results, however, have proved of value, not only to glaciologists but also to hydrologists, hydraulic engineers (making use of run-off from glaciers for economic purposes), and climatologists.

In 1914 the work of the Commission was stopped by the war, and co-ordinated effort ceased for a number of years. In 1927, however, at the invitation of the International Association of Scientific Hydrology, the Commission transferred its functions and its personnel to a new Commission Glaciologique created by the Association, and under these new auspices its work has been carried on ever since.

Meanwhile, at the Lisbon assembly, in 1933, the Association set up a Commission of Snow and appointed Prof. Church president of it. So rapidly did this Commission grow under the enthusiastic leadership of its president that by 1936, when the Association met in Edinburgh, it had become by far the largest and most active of all the commissions of the Association and had extended its field to cover all phenomena of snow and ice, with the exception of glacier variations. Overlap with the work of the Commission of Glaciers seemed almost inevitable, and so the question naturally arose whether consolidation of the two commissions would not in the end be mutually advantageous to them. Their union was approved by the Executive Committee of the Association at its meeting in April 1939 at Montreux, Switzerland, and so the way was paved for its final consummation at the Washington assembly.

Provision has been made within the new Commission of Snow and Glaciers for a permanent Committee on Glacier Measurements, which will continue the work previously carried on by the Commission of Glaciers, securing systematic records of the annual variations of glaciers. It is Prof. Church's intention to expand the scope of that work, which heretofore was restricted largely to Europe and the United States, so as to take in all of the more important glacier districts of the world, including the Andes of South America, the great mountain chains of Asia, the Alps of New Zealand, and the Arctic regions.

Aside from this enterprise the Commission has planned for the triennium ending in 1942 the following formal programme:

(1) Study of the origin, drift, and dissolution of icebergs, with reference to the forecasting of their seasonal appearance.

(2) Physical changes in the snow-cover conducive to run-off, especially floods.

(3) Study of the crystalline texture of glacier-ice in relation to the mode of movement of glaciers.

In addition, the following four special projects have been assigned to temporary committees:

(*a*) Standardization of maps of snow-cover and ice-cover for the world.

(*b*) Uniform classification of different types of snow and snow-cover, and uniform nomenclature for the same.

(*c*) A system of classification for the international bibliography of snow and ice.

(*d*) Standardization of methods of snow-surveying and forecasting run-off from snow.

TRAINING INDUSTRIAL WORKERS

IN *Occupational Psychology* (14, No. 1), B. Ungerson discusses the important problem of the training of industrial workers. In spite of the improvement in methods of training learners during recent years, there are still numerous organizations where the only method of training is to let the beginner copy an experienced worker, or he is told what to do and left to get on as best he may.

The resulting efficiency frequently falls short of what he might have attained. It is strange that while it is recognized that games are best learned under the tuition and guidance of an experienced teacher, industrial processes are so frequently allowed to be 'picked up'.

Ungerson divides industrial training into two sections: (1) acquiring knowledge about the job; (2) acquiring facility and speed in making the necessary movements.

The first includes knowledge of technical terms, the tools to use, how to deal with unusual circumstances; such knowledge can best be taught by a skilled teacher—not necessarily equivalent to the most skilled worker—whose primary business is teaching, not production, and who shall have the requisite qualities for teaching and be given adequate facilities.

In order to teach the correct movements the teacher should himself have a conscious knowledge of them, and for this, motion study is essential. By motion study knowledge is gained of the adequate and useless movements, so that the learner is instructed from the beginning in the right method, and thereby saved from having to unlearn unnecessary movements later.

The principles of motion study which are based on the physiology and psychology of habit formation are no longer a problem for research; it is their application that is needed.

The article is very well balanced and constructively critical, and is of immediate importance.

'SPIKE' DISEASE OF SANDAL

FOR many years after it was first reported in 1898 the so-called 'spike' disease of the sandal tree remained an enigma. Investigations were carried out in a desultory fashion, but no information of value resulted. It is only owing to its alarmingly rapid spread in many parts of the Madras Presidency and elsewhere in Mysore and Coorg that the work of the last few years has resulted in methods of control, the results of careful research work, being successfully elaborated and put into force.

In *Indian Forest Records* (New Series. Silviculture, 3, No. 7; 1939) appears a paper entitled "A Note on the Control and Eradication of New Outbreaks of the Spike Disease of Sandal (*Santalum album*)" by Rao Sahib S. Rangaswami and A. L. Griffith, Sylviculturist, Madras. The sandal, as is well known, is a root parasite which lives by haustorizing on the roots of other plants which act as hosts to it. These hosts may be many and varied, for the same sandal tree and the sandal haustoria may wander a considerable distance before a suitable host is found. The sandal tree is not necessarily parasitic on the plants growing nearest to it.

The action of the disease causes both new shoots and leaves to stand up stiff and bristle-like, from which the popular name was derived. The disease itself is a virus disease carried by insects which are probably between 1/20 in. and ¼ in. in size. In a diseased area the sources of infection are (*a*) diseased trees, (*b*) disease masking trees, and (*c*) insect vectors.

Factor (*a*) is removed by poisoning the diseased trees with 'Atlas Tree Killer' solution and thus killing them at once; factor (*b*) by tapping all the apparently healthy trees found in the diseased locality, and girdling and treating with poison all those that afterwards show the disease; and factor (*c*) is eliminated automatically, or the removal of the factors (*a*) and (*b*) naturally converts the viruliferous insects into non-viruliferous ones.

As indicating the rapidity of spread of this disease, in the North Salem Forest Division alone 'spike' first appeared in 1913. Twenty years later the infected area was 54,000 acres and in 1938 approximately 99,500 acres. Figures so far available indicate that the annual amounts spent on this research work have been but a fraction of the annual losses inflicted by the disease and of the sums saved. It is a classic example, as the authors say, "that 'academic' research can often be utilized by a practical forest department at a reasonably low additional expenditure to produce 'practical' results of immediate financial value". For quite contrary reasons the attention of the Governments of Burma and Nigeria may be directed to this valuable paper.

LYMPHATIC SYSTEM OF THE ANURA

A CONSIDERABLE amount of work on the lymphatic system of the lower vertebrates has been published in recent years. A recent treatise (*Amer. Anat. Mem.*, No. 18; 1939) is a survey of that work as it affects the Anura in particular. It is not simply a review of the literature, although this is fully taken into account and critically examined, but is also a description of the development of the lymph- and their relation to the blood-vessels, based upon hundreds of injections (both single and double) of five species of frogs, five species of urodeles, and two species of fish.

Dr. H. M. Knower, the author, first started investigating this problem in 1903, and in 1908 described a microinjector which has proved of considerable value in this rather difficult subject. The work is illustrated by forty excellent drawings on nineteen plates and five text-figures. The drawings are all of preparations of *Rana palustris*, save five which are of *R. catesbiana*. It is claimed that the method of injection, if carefully checked, provides a more satisfactory approach than the study of transverse sections of uninjected material, and with this most zoologists who have tried tracing these elusive vessels in sections will agree.

The first lymphatics appear when a complete blood circulatory system has been established, and are accessory or supplemental to the veins. They appear in connexion with the pronephric glands and the adjacent segmental glands, and this dorso-lateral plexus, in which the anterior lymph heart develops, drains into the pronephric sinus by a short vein. From this stage the development of the system is followed until the establishment of the definitive condition of the late tadpole. It is a pity that the zoological practice of putting specific names in italics has not been followed and that on p. 23, for example, *R. nig.* appears presumably for *R. nigromaculata*, and that throughout the name toad is used again presumably for some species of Bufo.

SEVENTY YEARS AGO

NATURE, vol. 2, May 12, 1870

A Building for the Learned Societies

THE Statistical Society has done good service to the cause of science in convening representatives of the learned societies, to consider whether it would not be possible to obtain a building for their accommodation worthy of the high position they occupy in this great metropolis. "Some of the societies have no reason to complain, the Royal Society, the Linnean, the Royal Astronomical, the Geological, the Chemical, the Society of Antiquaries, and a few others, are well accommodated, and a solid structure is being raised for them in Piccadilly."

The article goes on to point out that financial objections might be raised to a scheme for a new home for learned societies. To this the reply is that the Government should provide one or more buildings for the purpose. "Nowhere does the State do so little for science as in this country. The estimates for 1870–71 give the entire sum to be applied to the learned societies at 2,370 *l*—a sum distributed among very few of them. . . . In addition to this 160,000 *l* are appropriated to a building for certain learned societies in Burlington House; but it will serve for very few of them; and if we are rightly informed, the Government will reoccupy all the buildings in Somerset House now used by learned societies."

In the event that the Government refused to provide funds for a suitable building, the formation is suggested of a joint-stock company, the shares in which would be taken up by the members of the societies interested. "It has been estimated that the probable cost of a building sufficiently commodious, though not ornamental, in some eligible locality near Charing Cross, will be, with the ground-rent, 30,000 *l*. to 40,000 *l*."

Strange Noises heard at Sea off Grey Town

MR. CHARLES DENNEHY, of the R.M.S. *Shannon*, describes a peculiar noise heard on board iron vessels anchored off Grey Town, at the mouth of the River St. Juan, which separates Nicaragua from Costa Rica. Vessels are obliged to anchor in seven to eight fathoms of water outside the bar, and crews are regularly awakened at night by "a peculiar metallic vibratory sound". This noise, which commences "with a marvellous punctuality at about midnight", continues for about two hours with one or two very short intervals. The noise is not heard on shore, or on coppered wooden vessels. The bottom consists of a heavy dark sand and mud containing much vegetable matter brought down by the river. "The ship is undoubtedly one of the principal instruments in its production. She is in fact for the time being converted into a great musical sounding board."

The letter is followed by the brief comment: "Our correspondent should dredge.—Ed."

REFERENCE is made to the fact that a considerable number of papers are on hand at the Royal Society, and only two more meetings have been arranged for the session. Were not the present arrangements of the Royal Society meetings made to meet conditions long since passed away? And since the flow of papers into the Society has largely increased, why should not the outflow be a little accelerated?

FORTHCOMING EVENTS

[*Meetings marked with an asterisk are open to the public.*]

Tuesday, May 14

Royal Sanitary Institute, at 5 p.m.—Lieut.-Colonel J. A. Dixon: "Centralized Slaughtering" (Benjamin Ward Richardson Lecture).

Royal Institution, at 5.15 p.m.—Sir Frederick Keeble, F.R.S.: "The Development of the Home Production of Food".*

Thursday, May 16

Royal College of Surgeons of England, at 4 p.m.—Prof. A. D. Macdonald: "Experimental Spinal Anæsthesia".

Chemical Society (at the Institution of Mechanical Engineers), at 6 p.m.—Prof. W. N. Haworth, F.R.S.: "Recent Developments in the Chemistry of Carbohydrates" (Seventh Pedler Lecture).

Friday, May 17

Faraday Society (at the Royal School of Mines), at 2.30 p.m.—General Discussion on "The Hydrogen Bond".

(Speakers—Dr. W. T. Astbury, F.R.S.: "The Hydrogen Bond in Protein Structure"; Dr. C. E. H. Bawn, Prof. E. L. Hirst, F.R.S., and Dr. G. T. Young: "The Nature of the Bonds in Starch"; Dr. J. J. Fox and Dr. A. E. Martin: "Infra-Red Absorption of Hydroxyl Group in Relation to Inter- and Intramolecular Hydrogen Bonds"; Dr. J. M. Robertson: "X-Ray Evidence for the Hydrogen Bond"; Dr. G. B. B. M. Sutherland: "The Investigation of Hydrogen Bonds by Means of Infra-Red Spectra").

Royal Institution, at 9 p.m.—Prof. D. R. Hartree, F.R.S.: "A Great Calculating Machine; the Bush Differential Analyser and its Applications in Science and Industry."

Association of Teachers in Technical Institutions (Thirty-first Annual Conference, at the Hotel Russell, Russell Square, London), May 11–12.

May 12, at 10 a.m.—S. H. Moorfield: Presidential Address.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant in the Bacteriology Laboratory at Wray Castle—The Director, Freshwater Biological Association, Wray Castle, Ambleside, Westmorland (May 14).

Part-time Educational Psychologist—The Director of Education, Education Offices, 15 John Street, Sunderland (May 15).

Lecturer in Electrical Engineering Subjects at the Cardiff Technical College—The Director of Education, City Hall, Cardiff (May 16).

Director of Education and Inspector of Schools in the County Borough of Barnsley—The Director of Education, Education Department, Town Hall, Barnsley (May 17).

Construction Engineer for the Irrigation Department, Government of Ceylon—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9322) (May 17).

Demonstrators (Male) in the Department of Anatomy—The Secretary, King's College, Strand, W.C.2 (May 23).

Teacher for Colombo-British Institute, Bogota—The British Council, 3 Hanover Street, W.1 (quoting 'Colombia') (May 25).

Lecturer in Civil Engineering—The Registrar, King's College, Newcastle-upon-Tyne (May 31).

Lecturer in Plant Pathology and Zoology—The Principal, Swanley Horticultural College for Women, Swanley, Kent (May 31).

Assistant in the Department of Education—The Secretary, Queen's University, Belfast.

Technical Officers—The Chief Superintendent, Royal Aircraft Establishment, South Farnborough, Hants. (quoting Ref. A.500).

Assistants I (Ref. A.501), Assistants II (Ref. A.502), and Assistants III (Ref. A.503)—The Chief Superintendent, Royal Aircraft Establishment, South Farnborough, Hants. (quoting appropriate Ref. number).

Assistant Engineer for the Malayan Public Works Service—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9306).

CULTURAL RELATIONS OF FRANCE AND BRITAIN

THE cause for which NATURE stands, the disinterested pursuit of scientific inquiry, cannot recognize distinction of race, creed, language or nationality. Wherever the truly scientific spirit is at work, labourers in the intellectual field recognize one another as men and brethren ; and this is still the case, even in the distracted times in which we live. But here a tragic picture presents itself. What we have called the truly scientific spirit is wholly or partly quenched as soon as the lamp of freedom is extinguished. Freedom of thought and expression had been gained at a great price, and after centuries of persecution, in the chief civilized countries of the world. It has been temporarily lost in certain of the traditional and most influential homes of scientific and philosophic culture. In the words of M. Edouard Herriot, the dictators have killed in their countries the spirit of freedom and the idea of human dignity.

It falls, therefore, to the great democratic nations to uphold the banner of freedom. If they are to do so effectively, it must be through a deeper mutual understanding ; and in the long run such a result is really a question of education. It is essentially for that reason that steps have recently been taken by the responsible Ministries in Great Britain and in France to promote a sympathetic understanding of each other's aims and ideals in all educational institutions, and among all branches of the teaching profession, primary, secondary and university. In Great Britain it becomes one of our definite purposes to try to comprehend and appreciate the cultural position of our great ally.

At the close of the War of 1914–18, the general educational position in France closely resembled the position in Great Britain at the beginning of the century. After our Act of 1902, elementary schools no longer formed a water-tight compartment, having no connexion with secondary schools. But similar conditions remained unchallenged in France another dozen years or more. A French child of six entered either the local elementary school or the preparatory department of the *lycée*. The former was free, but the latter was not, and so at the age of six the educational destiny of the child was fixed, and depended upon the ability of his parents to pay fees. The vast majority of the children of France passed through the elementary schools until the age of thirteen, a small proportion remained for advanced courses, and a very few obtained scholarships at the *lycée* at the age of twelve. The barrier of class and wealth divided the elementary and secondary systems. The fortunate children (about one in ten) who entered preparatory departments at six proceeded at ten or eleven to the *lycée* proper, and at about seventeen took the *baccelauréat*, which gave access to the universities and other places of higher education. The *lycées* provided courses in classics, modern studies, and pure science, and were not vocational in any sense. Elementary and secondary teachers knew as little of each other as if they inhabited different countries. A queer sort of democracy, the reader may say ; however, like our own, it was and it is a democracy with a past.

But a profound educational stir took place during the last War and it is said that the idea of the far-reaching reform known as *l'école unique* was conceived by a group of officers in the trenches on the Western Front in 1917–18. Equal opportunities for all children, without regard to the means of their parents, was the fundamental feature of the reformers' demands. Sympathy and support came from many influential quarters, but long-established traditions die hard, and root-and-branch reform could not come quickly. For some years after the conclusion of the War the discussion was vigorously continued, and in 1927 a definite scheme was published, taking the form of a parliamentary Bill. It was this scheme which substantially became the law of the land in 1937, when M. Jean Zay was Minister for Education in the Popular Front Government.

The details of the new law, the operation of which is inevitably slowed down by the outbreak of the present War, can here be only briefly summarized. Similar courses of instruction are provided in all schools for children between six and twelve. At the latter age, tests are applied which determine whether a child continues his primary course to a higher stage or starts upon a secondary course. In the latter event he enters the *classe d'orientation* for a year, during which the kind of further education for which he is best fitted is settled. This *classe d'orientation* is from the point of view of British teachers the most remarkable feature of the system, and its working will no doubt be carefully watched, now that opportunities of exchange of duties with French teachers are being increased. In France itself the innovation has been subjected to adverse criticism, but the experiment is being very carefully conducted. This introductory year having been completed, the pupil enters upon a course either in classical or in modern or in technical humanities, the differences between the three being gradually made by increasing emphasis in one of the three directions. The gradual abolition of fees in the case of students who reach scholarship standard brings within sight in France what Mr. Harold Nicolson, M.P., in a recent broadcast talk, has advocated for England—a classless education.

From the point of view of NATURE, perhaps the most interesting and important thing yet remains to be said. Throughout his course, it will be observed, the pupil is engaged upon the humanities, with gradually increasing stress upon the classical or modern or technical side—but always the humanities. In Anglo-Saxon countries, specialization may be carried so far that from a too early age a boy devotes himself so much to what may be found inside a laboratory that, unless his home opportunities are uncommonly good, he may develop into something which one hesitates to call an educated man. From that position the French tradition of general culture is a safeguard. The more one studies the history of educational changes and controversies in France, the more deeply impressed one becomes by the steadfast adherence of the French mind to that tradition. For three centuries, including the Revolution, the Napoleonic era and the Restoration, the old classical tradition remained intact, partly to secure secondary education as a privilege for the upper and middle classes, but partly also because nothing satisfactory was found to take its place. A change was bound to come, as Matthew Arnold foresaw in 1865, but it came slowly. The legacy left by the classical tradition is seen in the continued determination that French culture, which led the way in Europe for centuries, shall be preserved. To quote Prof. Kandel, an American authority on comparative education, it is through "*études désintéressées*" (general studies), that French secondary education "aims to cultivate judgment, taste, appreciation, and an ability to think clearly and logically. . . . More concretely expressed, the measure of a sound liberal education is the ability to speak well and to write well, as the outward indication of clear thinking".

More recently, Prof. Kandel has, in his capacity as editor of the 1939 report of the International Institute, Teachers College, Columbia University, brought together two statements by distinguished Frenchmen on the meaning of a liberal education in France in the twentieth century. One of these authorities, the Director of the École Normale Supérieure, though making concessions to the modernists, ends by declaring that the advocates of a liberal education based on a general classical culture, if they must yield any territory, will put up a fierce resistance, relying on a tradition of which France is proud. The other, a professor at the Lycée de Versailles, and general secretary of Les Compagnons de l'Université Nouvelle, equally maintains that a liberal education should subordinate the acquisition of knowledge to the task of so educating the mind as to enable it to attain to as broad and deep a culture as possible. But he denounces the exclusively literary tradition as exhibiting a blind faith in a single ideal supposed to lie beyond discussion. He charges the advocates of that tradition with showing profound ignorance of the vast extensions of the human spirit as a result of the development of experimental sciences since the sixteenth century, and with slighting "the remarkable educative value of the use of the experimental methods for intellectual training". We think the flowing tide is with the modernists.

There, however, we must leave the matter, trusting to have said enough to suggest the immense importance of supplementing the defensive and economic relations of Great Britain and France by a better understanding than ever before of the educational aims and aspirations of the two countries. As M. Sarraut has recently said to the educational leaders of France, the spirit of sympathy and cordiality for the people of the Allied countries must be created among all young people from school children to university students. There can, he wisely added, be no question of exercising any pressure in influencing their minds. Neither familiarity nor affection can be imposed. But we can prepare the ground which favours their development, and this is less perhaps a matter of direct teaching than of providing opportunities of bringing about an intuitive understanding.

A GREAT PSYCHOLOGIST OF SEX

My Life
By Havelock Ellis. Pp. xviii + 542 + 8 plates. (London and Toronto: William Heinemann, Ltd., 1940.) 15*s*. net.

HERE we have the life-story of one who, with many other literary and cultural achievements to his credit, will be known above all as the man who made it his chief work to bring sanity into the sphere of sex and to remove those taboos which had hitherto kept sex so largely outside the pale of impartial scientific thought. This autobiography is no mere product of the author's declining days; it is the fulfilment of a project formed in early life, a project that, like all his other enterprises, came slowly but steadily to fruition, being written at what he judged to be the most favourable moments from the age of forty onwards. Ellis indeed held autobiography in high esteem; it was his view that "of all forms of prose, outside the limits of imaginative art, there is no other form so precious in its nature and so permanent in its value". There can be little doubt that the book does well and truly fulfil its author's purpose. Although it is unlikely that it will ever be considered one of the world's very few imperishable monuments of self revelation, it yet provides a sympathetic and illuminating picture of a delicate, sensitive and philosophic being, who was willing to accept himself with the capacities and limitations that Nature had provided, and who understood well how to reconcile himself to his limitations and to make the most of his capacities—a task that few accomplish with so good a grace and in such ample measure.

More than half of the book is concerned with the years of his marriage, and this provides a fascinating study of the long union of two very dissimilar personalities—the retiring, methodical, introvert Havelock, and the gifted but tempestuous extravert Edith (née Lees) who was his wife—a union further complicated by the existence of a strong homosexual tendency in the latter partner, though at the same time one that was firmly cemented by a deep personal affection and a lively common concern for the welfare and progress of humanity. With the death of Mrs. Ellis in 1916 (after an illness that affected both her mental and her physical health) the detailed story ends, and but a few pages are devoted to the remaining twenty-three years of his life. His marriage ended and his major self-appointed task accomplished (the last of the six original volumes of the "Studies in the Psychology of Sex" was completed in 1910, though a supplementary seventh volume appeared in 1928), he felt he had drunk deeply of the well of life and could afford to enjoy in relative tranquillity such years as yet remained. These years, filled with loving companionship, with tender memories, and with the sense of a task well accomplished and in its outcome successful beyond all expectation, were very happy ones, and the book ends on a note of optimism that nowadays is rarely to be met with. In an age in which we are beginning to look back with nostalgic longing to the calm days of the later nineteenth century, it is cheering and refreshing to realize that, in the eyes of one who lived and strove in those days, our modern world, for all its insecurity and manifest disorder, holds many compensations—compensations which to Ellis were the greater in as much as he felt that he himself had contributed to their existence.

Many readers will regret that the book does not deal more fully with the author's intellectual development and the emotional factors underlying it. We are, it is true, told how, as a young man of about twenty, he had already dimly formed the project which afterwards found fulfilment in his *magnum opus*. Looking back some fifty years he recognized that "here had come a youth whose impulse it was to intellectualize and moralize his own personal situation, thereby transferring it into an impersonal form and universalising it"; but we learn all too little as to how his thought developed as the work progressed. We know of the paramount importance of the writings of James Hinton for his early years, but we are told almost nothing about his reactions to the great movements, events and figures of his own time; there is no mention, for example, of his great contemporary Freud, whose work lay so largely in the same field as that of Ellis himself. For more enlightenment in these directions, we would perhaps willingly have sacrificed some of the rather speculative reflections on hereditary influences that fill a good many of the early pages and some of the letters to and from his wife that are found in such abundance in the later chapters. But an autobiographer has clearly the right to say what seems to him of chief importance, and, taken all in all, this book constitutes a worthy monument to a noble and prolific life.

J. C. FLUGEL.

ATMOSPHERIC AND TERRESTRIAL PHYSICS

Physik der Atmosphäre

Herausgegeben von V. Conrad. Bearbeitet von J. Zenneck, Rudolf Steinmaurer, P. Gruner, H. Landsberg, F. W. Paul Götz. (Ergebnisse der kosmischen Physik, Band 3.) Pp. xi + 333. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1938.) 32 gold marks.

Gerland's Beiträge zur Geophysik, Supplementband 4

Ergebnisse der kosmischen Physik, Band 4: Physik der Hydro- und Lithosphäre. Herausgegeben von V. Conrad. Pp. x + 293. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1939.) 31 gold marks.

IN 1931 appeared the first volume of the series "Ergebnisse der kosmischen Physik mit Einschluss der Geophysik", being a supplementary volume to Gerland's "Beiträge zur Geophysik". It contained a series of excellent articles, on the aurora, cosmic rays, ozone, sound propagation, the earth's figure, and wave-motions. A second volume appeared in 1934, containing articles on glaciers, atmospheric ionization, gravity, seismology, cosmic rays, and earth faults. These two volumes, edited by Conrad and Weickmann, were finely produced by the Leipzig Akademische Verlagsgesellschaft.

Two new volumes have since appeared, produced in the same fine style as before, under the sole editorship of Conrad, now in the United States, a refugee from Austria. The price-level remains at the high figure which practically precludes most readers from possessing copies of their own, and forces them to resort to library copies (perhaps consoled by the reflection that the contributors' remuneration was probably more generous than is usually accorded to those who perform this valuable public service of reporting on developing topical branches of science). The quality of the contributors and their work also preserves substantially the standard of the two previous volumes. A somewhat different plan of editing has been followed, however, in that volume 3 deals exclusively with atmospheric physics, and volume 4 with non-atmospheric subjects.

Volume 3 contains five articles; the first, written by Zenneck with much freshness and lucidity, is on the ionosphere (37 pp.), the second (75 pp.), by Steinmaurer, on cosmic ray studies during the years 1933–37, the third (42 pp.), by Gruner, on dawn phenomena, next a small treatise, by Landsberg, on condensation nuclei (98 pp.), and finally a continuation (73 pp.), by Götz, of his excellent article on ozone in volume 1. Each article contains its own bibliography, which in most cases ends with 1937 references; there is, for example, no reference to mesons and their instability, in connexion with the barometric effect on cosmic rays. There is an authors' index to the whole volume, but no subject index. Similar remarks apply to volume 4.

Volume 4 opens with a 74-page article by Ekman on convective streams in the oceans; the remaining articles deal with the physics of the solid earth. Jeffreys discusses deep-focus earthquakes (31 pp.), Tsuboi writes on crustal deformations as indicated by geodetic measurements (63 pp.), Gutenberg on the development of seismic prospecting methods (50 pp.), and the volume concludes with a somewhat curious article (71 pp.), by Fritsch, on "the structure and properties of geological conductors", dealing with their electrical resistivity, earth currents, and the underground reception of radio waves.

All the articles are written in German except three—those by Landsberg (volume 3) and by Jeffreys and Tsuboi (volume 4)—which are in English.

PHENOMENOLOGY OF LITERATURE

The Growth of Literature
By H. Munro Chadwick and N. Kershaw Chadwick. Vol. 3. Pp. xxvi + 928. (Cambridge: At the University Press, 1940.) 35*s.* net.

THIS bulky and well-printed volume concludes the ambitious enterprise of its authors to give a history, illustrated by abundant examples, of the origin and growth of literature from what they call the 'heroic' ages of various peoples down to the time when, owing to the general knowledge of reading and writing and the improved communications between different nations, compositions, whether intended to instruct or delight, take on the forms with which Europe has been familiar, at least in its more civilized regions, for the last couple of millennia. In short, the work deals largely with that literature which existed, and here and there continues to exist, without the aid of letters or with but a minimum of help from them.

Having examined the early European literatures in the first volume and those of India, the Hebrews and the Slavs in the second, the authors devote this third volume mostly to a survey of the 'oral' literatures of the Tatars, the Polynesians, with some twenty pages added to sketch that of the Ibans or Sea Dyaks, and a few African peoples. With that frankness and lack of pretence which is one of the best features of their work, they point out their own involuntary deficiencies, the causes of which range from the difficulty of procuring from Russian booksellers recent monographs on Tatar culture to the sheer non-existence of records of the doings of many African peoples, at least so far as their songs and stories are concerned. It has been indeed a defect of many collectors that, when getting together material from their chosen fields, they have paid attention too exclusively to folk-tales (not noticed in this work, as being in their nature international) and not sought as diligently as they might for beginnings of higher forms which might one day develop into epics or hymns, the products of courtly or priestly circles. But with these defects, and others which must needs arise in a treatise covering so many linguistic areas, the work is still a most valuable repository of well-commented information on its subject. It may claim to be the most complete account yet given of what may be styled the phenomenology or typology of literature, within the limits of study which the authors have set themselves.

It may, however, be questioned whether it is in any proper sense a history of early literature, or indeed whether such a history is possible for anyone, however learned, to produce in the present state of our knowledge. We are shown abundantly that the various types of composition examined (there is an elaborate classification, repeatedly explained, of the different *genres*) exist in sundry parts of the world. We are given several short specimens of each type from each area and good synopses of other works. Speculations are modestly put forward as to the conditions favourable to their growth and the kinds of society which produced them. Here and there (as on p. 409, which discusses the affinities of Polynesian and Japanese poetry) we are at least furnished with material for investigating a historical connexion between one area and another. The question of diffusion or polygenesis is fairly faced, more than once (as on pp. xxiii, 216–18, 495–6).

All these are necessary steps toward constructing a history of early literature, but not yet the history itself. It may be seriously doubted whether the most diligent student of the book could write an accurate sketch of the process by which, given a certain environment, this or that type might be expected to appear, the conditions under which it would naturally give place to another and the extent to which it will co-exist with a third. Indeed, since the subject is the doings of man, which are in the last resort unpredictable, it is reasonable to doubt whether such a feat will ever be possible. But, even with the help of the last two hundred odd pages of this volume, devoted to a "general survey" of the subject, it is scarcely true that the less ambitious task of showing how, in fact, the literary forms have hitherto come about has been completed.

This is not meant to be derogatory to the authors; it merely states that they have not achieved what the reviewer believes to be impossible. Some part of that task they have accomplished, and this is no small praise. They have shown, for example, that 'heroic' poetry, that of more or less epic type, is the offspring of what they call 'heroic' society, for example, that stage of barbarism in which the ruling class is warlike, predatory and as a rule illiterate. Its necessary subject-matter appears to be raids and wars waged at least partly with a view to plunder, with elementary tactics and strategy, giving much scope for the courage or cunning of the individual chieftain. It is, however, the fact that they have pressed this principle too far, and come out to some theories of the growth of the "Iliad" and "Odyssey" (see p. 770), which confuse the activities of the Ionian Homer, a man of comparatively high civilization, with those of the ruder minstrels who went before him. That is to say, they confound the early literary epic with the hero-ballad or the nascent epics to which it often gives rise. On p. 886, when the authorship of certain kinds of oral literature is referred (correctly, no doubt, for many countries) to a priestly class, it is forgotten that no such class existed in Greece. If this were a classical journal, some other inadequacies in this sphere might be pointed out; here it is enough to say that they are small and not very numerous, quite outweighed by the abundant light thrown on that and other areas.

In short, where the authors succeed, they deserve their success; where they seem to the reviewer to have failed, it is doubtful whether any amount of diligence or erudition would have done better.

H. J. ROSE.

BEHAVIOUR OF THE UTERUS

Physiology of the Uterus

With Clinical Correlations. By Prof. S. R. M. Reynolds. Pp. xx + 447. (London: Hamish Hamilton, Ltd., 1939.) 42*s.* net.

THE publication of a book entirely devoted to the behaviour of the uterus is an index of the remarkable advances that the last few years have seen in knowledge of reproductive physiology. Dr. Reynolds is a distinguished investigator of the problem of uterine motility, and while this topic is given great prominence, it cannot be said to be over-emphasized, and an excellent balance is maintained throughout the book between all aspects of uterine physiology.

The monograph opens with a brief account of the topography and anatomy of the Fallopian tubes and uterus, and with a description of the various patterns of contractility to which they are subject in the non-pregnant, pregnant, and parturient individual. The hormonal and other factors which control these patterns are then discussed, after which the author deals with the problem of uterine growth, laying particular emphasis on the nature of the growth which occurs in pregnancy, and on the factors responsible for it. The circulatory changes which take place in the uterus, their hormonal control, and their relation to the process of menstruation are reviewed in detail, and the problem of uterine metabolism is also dealt with. The book closes with a section devoted to the hormonal therapy of uterine disturbances.

The volume is a notable record of the scientific advances that have been made in the laboratory study of a subject which until recently has been the domain of clinical gynæcologists only. There can be little of value in the literature which has been overlooked by Dr. Reynolds, and his achievement may well serve as a stimulus and a model for further reviews of other fields of endocrinology and reproductive physiology.

AMERICAN NURSERY PRACTICE

Propagation of Horticultural Plants

By Guy W. Adriance and Prof. Fred R. Brison. (McGraw-Hill Publications in the Agricultural Sciences.) Pp. ix+314. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 20*s.*

THIS is a new American text-book dealing with the various methods employed in the multiplication of cultivated plants. After a short elementary introduction to the structure and function of plant organs, including the flower and its parts, chapters are devoted to 'layerage', 'cuttage', 'graftage', and other methods. Throughout, the text reads clearly; the descriptions are brief and direct. Modern methods are advocated, and the necessary equipment for carrying out the work is always described. However, the allocation of space is somewhat uneven; for example, the propagation of lilies, investigated and reported upon in America, is more fully dealt with in the text and by illustrations than that of hyacinths, studied by the Dutch, of which there is but brief mention and no illustration. Also the index contains no references to hyacinths. Root cuttings, leaf cuttings, and the propagation of ferns from spores are not dealt with.

Common names of American plants and diseases are frequently used. These may be unfamiliar to some English readers ; the legends to Fig. 105 and Fig. 106, to which no further reference in the text is made, read "A live oak top growing on a post oak rootstock" and "Upper part of this tree is live oak, top worked on to a post oak". In both illustrations posts are also shown, so that some confusion may arise, for every reader will not realize that *Quercus Virginiana* and *Q. stellata* are the plants concerned.

There is a useful chapter dealing with the relation of propagation practice to diseases. This could, with some advantage, be extended to include more pathology, for "Phony peach" conveys little, and the reader is not informed that it may be a virus disease. The grape root louse (Phylloxera) and woolly aphis are included in this chapter on 'diseases'.

There are selected short lists of references, most of which are to American publications, for the several chapters, but the questions at the end of each chapter are of doubtful value. The index would be improved by the inclusion of Latin names. As it briefly surveys a wide field, this will prove a useful book for students desirous of learning the outlines of American nursery methods.

M. A. H. T.

ANIMAL HORMONES

Hormones in Invertebrates
By Prof. Bertil Hanström. (Monographs on Animal Biology.) Pp. x + 198 + 13 plates. (Oxford : Clarendon Press ; London : Oxford University Press, 1939.) 12*s*. 6*d*. net.

OF recent years increasing attention has been paid to invertebrates to determine whether they provide evidence of chemical correlation similar to those hormonal reactions that are now recognized as being of tremendous physiological and philosophical importance in the life of man and other vertebrates. Even in 1933 the view was held by some workers that no clearly demonstrated incretory activity in invertebrates, nor any demonstrable influence of vertebrate hormones on invertebrates, had up to that time been found.

Since that time an ocean of endocrinological investigations has been charted, and here Prof. Bertil Hanström has found it useful to present in collated form a more or less complete summary of what is known at present about hormonal reactions in invertebrates. It is now realized that in invertebrates the presence of several incretory organs and many physiological processes cannot be explained without adopting the hypothesis of hormonal action. These investigations show that the previously accepted definition of a hormone as a substance which is secreted into the blood-stream by an endocrine organ, and which exerts a specific effect at another place in the body, is no longer tenable. The absence of blood in many invertebrates and the production of hormonal substances not in incretory glands but in portions of organs the chief function of which is quite other than hormonal, the hypotheses of 'gene hormones', 'growth hormones', 'wound hormones', 'organizers', etc., are evidence that a new hormonal concept should be adduced. In this work Hanström has accepted Köller's hypothesis of considering a hormone as an organic substance which is produced by the organism for its own use, and which has a specific regulatory function within it. As the author suggests, it is clear from the evidence already obtained, which is set out so lucidly in this monograph, that at least some invertebrate hormones may one day be used for important experimental and perhaps pharmacological purposes in vertebrates, including man.

The value of this book to endocrinologists no one would gainsay, but for the non-specialist it is lacking in appeal. In addition to presenting this comprehensive epitome of present-day knowledge, the author might have attempted to introduce a little hypothetical argument when discriminating between apparently diverse statements of fact. For this reason the book, which deals with a fascinating topic, loses a great deal of its attraction for the non-endocrinologist.

The literature index is comprehensive and up to date, but since a considerable portion of the book is given over to the discussion of the influence of vertebrate hormones on invertebrates, it is surprising that the author has omitted any reference to Szent-Györgyi's work on the relations between hormones, vitamins and enzymes. Some original plates make up a volume that must remain as a source-book of information for some time. Incidentally, the book is the first of a new series of monographs on animal biology.

T. H. HAWKINS.

GEOPHYSICAL STUDY OF SUBMARINE GEOLOGY*

BY DR. E. C. BULLARD,

SMITHSONIAN RESEARCH FELLOW OF THE ROYAL SOCIETY

TWO thirds of the earth's surface are covered by water. Our direct knowledge of the geology of this area is derived from samples obtained by lowering grabs and similar instruments on to the sea bottom. To realize the inadequacy of this evidence we have only to consider how little we should know of the past history and structure of the continents if our information were confined to that which could be obtained from a few thousand samples of surface soil collected from points scattered over the earth. In recent years a number of methods have been developed for finding out something about the form, constitution, and structure of the rocks hidden beneath the sea. These methods form part of geophysics, that is to say, they involve the application of techniques derived from physics to solve problems about the earth.

By merely examining a map of a piece of country, it is often possible to say something of its more recent history, for the form of the surface is a consequence of its constitution and history. Further, an adequate map is an essential basis on which to plot lithological and structural information.

The first problem of submarine geology is therefore to devise methods of making maps of the ocean with a detail and accuracy comparable with the maps of land areas. In doing this, two things have to be determined, (*a*) the depth of the sea, and (*b*) the position at which the depth is measured. The measurement of depth is easily and rapidly carried out with the echo sounder. In the type of instrument developed by the Admiralty, a pulse of supersonic sound is produced by a magnetostriction oscillator attached to the bottom of the ship. The sound travels to the bottom of the sea where part of it is reflected. The reflected part returns to the oscillator, which acts as a microphone and records the arrival of the pulse on a moving piece of paper. In this way a continuous record of the time taken for the echo to return can be made, and if the velocity of sound in sea water is known, this gives a continuous profile of the route over which the ship has steamed.

The determination of the position of the ship when the sounding is made is considerably more difficult if the ship is out of sight of land. Wind and currents soon cause a course steered by dead reckoning to become uncertain by several miles, and astronomical position finding can involve considerable errors and is not always possible. To overcome these difficulties the method of 'taut wire' control has been developed. In this method a number of mutually intervisible buoys are laid, and the distances between them determined by running out piano wire from a drum on the ship and measuring the length run out by passing it over a measuring sheave. This method gives an accuracy of the order of one in a thousand, but is too elaborate to use for any purpose beyond the fixing of the positions of a few control points for use in the detailed survey. The position of the ship when taking a sounding may be found by observations on three buoys in known positions, but this requires good visibility and a close network of buoys.

To obviate this difficulty, the United States Coast and Geodetic Survey has developed the method of 'radio-acoustic ranging'. A small bomb is thrown from the ship the position of which it is desired to determine. The sound from the bomb travels through the sea and actuates a microphone suspended from a buoy. The microphone is connected to a wireless transmitter in the buoy which signals the instant of arrival of the sound. Thus, if the original explosion and the arrival of the wireless signal are recorded on the ship, the time interval between them will give a measure of the distance of the ship from the buoy. If there are two or more such buoys in known positions, the position of the ship may be found with an accuracy of a few tenths of a mile. In the practical application of this method, a bomb is thrown overboard about every six minutes, so that the position of the ship is found about once every mile. In the past few years, the greater part of the waters around the United States have been mapped by such methods out to the thousand-fathom line.

The seas around the continents almost invariably consist of a comparatively shallow 'Continental Shelf' sloping very gently to 100 fathoms in a distance of 50–200 miles, that is, with an average slope of a tenth to a fortieth of a degree. At about the 100-fathom line, the slope suddenly steepens to about 4°, and in a few miles the sea deepens to 1,000–2,000 fathoms. The American surveys give a map of this area on a scale of two miles to one inch. These maps have brought to light several remarkable features. First, there is a very sharp demarcation between the shelf and the slope at its outer edge ; when sailing outwards from the continent the sudden change of slope is very conspicuous on the echo sounder, and its start can be placed on the record within a few hundred yards. Secondly, the sloping edge of the shelf is cut into by a remarkable series of submarine valleys. The existence off the coast of America and elsewhere of these valleys has been known for many years, but it is only recently that much attention has been paid to them. They are steep-sided features generally with flat bottoms, often lying several thousand feet below the level of the sea bottom on each side.

---

* Substance of a Friday Evening Discourse delivered at the Royal Institution on April 26.

The origin of these features has been the subject of considerable controversy. It has been maintained that they were cut by rivers at a time when the level of the sea was much lower than at present. The recent surveys, which show the valleys to extend to the 1,000-fathom line, make the necessary lowering of the sea so great that this hypothesis must be abandoned. The difficulties of supposing the land to have been raised 6,000 ft. and lowered again are no less severe. Such a change must have left its mark on the flat-lying sediments of the coastal plain and have caused changes in the drainage which would be apparent in the present-day physiography. We are therefore compelled to believe that the valleys were formed under the sea. Unfortunately, very little is known of submarine erosional processes, largely owing to the lack of detailed surveys and to our scanty knowledge of the nature of the rocks forming the submarine topography..

It is, in fact, not possible to discuss these questions profitably without more information about the nature of the rocks forming the sea floor. Cores up to ten feet long have recently been secured from these rocks by firing a tube into the bottom from a gun lowered from a ship. Such methods are of great importance, but we can scarcely hope to obtain by their aid information about rocks more than a few tens of feet below the bottom of the sea. To penetrate deeper, indirect methods must be used. The most promising of these is the seismic method. In this, charges of explosive are detonated on the sea bottom and the elastic waves produced are recorded by seismographs also placed on the bottom. When an explosion is made, waves spread out from it in all directions, and from the time taken for the waves to travel a known distance their velocity may be found and an indication obtained of the nature of the rock through which they have travelled.

Reflexions of waves from the interfaces between hard and soft rock may also be observed. If a layer of a soft rock in which the velocity of the waves is relatively slow overlies a hard rock in which the velocity is high, it is possible for a wave to travel down to the hard rock, along in it, and up again in a shorter time than it can traverse the direct path through the soft rock. It is on the observation of such 'refracted' waves that the work done at sea depends. Measurements have been made off the eastern coast of the United States, and to the west of the British Isles, with broadly similar results. In the case of the British Isles, igneous and well-consolidated sedimentary rocks are exposed on land, and measurements at sea near the shore show them to be covered by only a few feet of recent sediments. On going farther from shore the thickness of the sediments increases steadily until at the 100-fathom line about 150 miles out to sea, the hard rocks are buried beneath more than 8,000 ft. of sediments. Beyond this it was not possible to go with the facilities available, but if the surface of the hard rock be extrapolated for a few miles, it runs over smoothly into the floor of the deep ocean.

It therefore seems that the Continental Shelf is a mass of sediments lying on a gently sloping surface of solid rock, and that the edge of the shelf is simply the edge of the sediments and does not represent a fault line dividing the ocean from the continent. This suggests that the Continental Shelf is growing seaward by deposition of the sediments worn from the land, the level of its surface being determined by the level at which the sediments can just rest without being disturbed by currents and wave motion. If this picture be correct, a particle of sediment brought down by a river is washed hither and thither on the sea floor until at last it comes to rest beyond the edge of the Shelf in water so deep and still that it can no longer be moved. It is probable that such a process would result in the deposition of sediments at an angle too steep for stability and that landslips would occur producing the jumbled topography typical of the edge of the Shelf. Great masses of rocks showing signs of contortion while plastic would also be produced ; such rocks have been found in many parts of the world, and may well have been produced in this way.

Measurements of gravity over the Continental Shelf should also give useful information. Unfortunately, only a few measurements have so far been made ; these show, rather unexpectedly, that the sediments are in isostatic equilibrium ; that is to say, the crust has sunk under their weight, until it is in equilibrium.

Present technique can give much information about the geology of the shallow seas, but these form only a small proportion of the whole. The outstanding problem is to develop accurate methods of position-finding far out at sea, so that accurate surveys can be carried out in mid-ocean, and to develop a variation of the seismic method that can be used in deep water. A start has been made with this work, and when conditions again allow experiments at sea, there is little doubt that rapid progress will be made. The problems to be studied are of great importance for geology. The mapping of a section of the mid-Atlantic Ridge, for example, together with determinations of the velocities of elastic waves in it, could not fail to yield results of great interest. We know already that it includes features which are on a scale comparable with the Himalayas, and such a survey would indicate whether these mountains were a folded range that had never been exposed to denudation, a sunken land mass, or a system of submarine volcanoes. The major rival geological theories, such as the permanence of ocean basins and Continental Drift, involve theories about the oceans. As they are derived almost entirely from data obtained on land, the study of the other two thirds of the earth's surface may be expected to be illuminating.

BORON IN AGRICULTURAL AND HORTICULTURAL PRACTICE

DURING the past year some three hundred and fifty papers and articles relating to the uses of boron compounds in agriculture and horticulture were published in twenty-one different countries. Nearly half of these contributions were made in the United States, where the rapidly growing interest in the subject was particularly marked. According to a recent report, boron investigations covering a wide range of soils and crops are now in progress in at least twenty-six American States. Important among the new findings published in the United States during the year was the efficacy of applications of boron to the soil in controlling canker disease, also termed girdle or internal black spot, of table or canning beet. The disorder appears to be closely related to heart rot, the well-known boron deficiency disease of sugar beet and mangolds. Canker is said to be very prevalent and of considerable economic importance in the canning beet growing districts in the States of New York, Michigan, Oregon and Wisconsin. Its presence has also been observed in Washington State.

The beneficial use of boron on daffodils was reported from North Carolina, and further advance was made in New York State in the study of internal bark necrosis of apple trees and its control by the application of boron. A first progress report on drouth spot of prunes was also issued in the latter State. The first recorded instance of boron deficiency in cabbage and related crops, under field conditions, was reported from Wisconsin. The disorder, an internal breakdown of the stem in the region of the core, was largely controlled by the application of boron. In Florida, the condition of citrus trees in several groves is considered to suggest a lack of boron. An investigation of this possibility has been begun. An apparently new disorder of tomato plants, experienced in New Jersey, and characterized by a form of yellowing of the leaves, was controlled by suitable applications of boron. In the same State, the first recorded symptoms of boron deficiency in roses grown in sand cultures were described.

Three important reviews of literature were published in the United States during the year. The first supplement to the American Potash Institute's Bibliography of Literature "Boron as a Plant Nutrient" was issued in May and listed 171 papers reviewed during the period July to December, 1938. The Chilean Nitrate Educational Bureau Inc., New York, published the third edition of its well-known "Bibliography of References to Literature on the Minor Elements". This lists 449 papers relating to boron. A booklet entitled "Boron in Agriculture", published by the Pacific Coast Borax Company, New York, presents a concise and well-illustrated review of work conducted in the United States and Canada.

In New Zealand and Australia the list of crops which may suffer from boron deficiency under field conditions was also extended. In the former country, workers at the Cawthron Institute found that a disorder of apricot fruits, which is sometimes prevalent in the orchards there, is due to lack of boron and can be controlled by the addition of boron to the soil or by spraying it on to the tree. The disorder in question has been termed 'brown spotting'. Further investigation of the subject is in progress. In Queensland, Australia, a condition of young pineapple plants, known as 'crookneck' (so called on account of the manner in which the heart leaves are twisted) was largely controlled by spraying the plants with boron. Progress was reported from New South Wales concerning the investigations being conducted there on needle fusion of pines. The application of boron to diseased trees has given complete or partial recovery in some cases, but in others has so far been without result. This disorder of pines also received further attention in Great Britain, where it was shown that the leaves of affected trees contained consistently less boron than did those of healthy trees. The results of additional investigations concerning the control of brown heart of swedes in New Zealand by the use of boron were reported. It was stated, too, that the use of boron for the control of cork disorders of apples in New Zealand is likely to have wide application in the Alexandra district of Central Otago.

Other notable contributions came from the Dutch East Indies and Holland. The symptoms of boron deficiency in coffee have been studied at the Besoeki Experiment Station in Java, and similar investigations on potatoes under both laboratory and field conditions were carried out in Holland. French workers extended their investigations to a study of the boron content of various types of soil, and have published their first results. Work in Canada related to swedes and turnips more particularly, and the use of boron there on additional crops is now being studied.

The Institute for Tobacco Research of the German Reich has investigated the essential nature of boron for the healthy growth of tobacco. As a result boron has been applied to its tobacco fields for some years, with good results. The well-known German worker, Brandenburg, published early in the year a review in German of available information concerning the use of boron in plant nutrition, with special reference to his own investigations. It was also reported from Germany that the production of borated superphosphate for use on the sugar beet crop in 1938 was 30,000 tons, compared with 20,000 tons in 1937. Another noteworthy feature was the publication by several workers in the United States, in Germany and in Great Britain of methods relating to the determination of boron in soils, plants and fertilizer materials.

Important developments, in addition to those already mentioned, took place in the British Isles. Further successful results relating to the control of brown heart in swedes and turnips by the use of boron were reported from Northern Ireland, the north-east of Scotland, and the north-west of England, in experiments carried out in 1938. These were the first investigations in the areas concerned. The disease was also reported to have been prevalent in Devon and Cornwall. In an experiment in Scotland in 1938, boron (applied as 'Boronite') gave a large measure of control of internal rust spot of potatoes.

Special mention must also be made of the publication early in the year, of the third of the reviews "Boron and Plant Life" (*Fert. Feed. J.*, February–April, 1939.) This review, written by A. C. and R. W. G. Dennis, summarized developments reported in some two hundred papers during the latter half of 1937 and in 1938. The article was later published in French.

The foregoing is naturally only a brief outline of some of the more important items of information reported. It may serve, however, to indicate the wide range and extent of investigational work on boron now in progress and to record the more important advances recently made.

SOME EXPERIMENTS IN RABBIT CONTROL

BY R. M. LOCKLEY,

SKOKHOLM ISLAND, PEMBROKESHIRE

ATTEMPTS have been made over a period of twelve years to control and if possible exterminate the wild rabbit *Oryctolagus cuniculus* on the island of Skokholm, Pembrokeshire, so as to reserve pasture for other livestock.

Skokholm is composed almost entirely of Old Red Sandstone rising to an average height of 100 ft. above sea-level, is rock-bound, and often inaccessible in bad or moderate weather owing to its exposure to the strong Bristol Channel tides and the open Atlantic. The island was once a general farm (1800), but is now covered with rough grazings of rabbit-worn turf, heather, bracken and thrift. There are about 200 acres of rough grazings and some 42 acres of broken-up cliff ground and outcropping rock. So far back as 1324 rabbits were marketed from the island ("Inquisition post mortem" of Aymer de Valence, Earl of Pembroke. 18 Edward II, No. 75), and later records show no break in the occupation of the island by rabbits up to the present day. This isolation in an exposed situation over centuries has produced a type weighing about four ounces less than the typical rabbit on the mainland of Pembrokeshire, from which the present-day Skokholm rabbit further differs in possessing a more plentiful admixture of black hairs on its upper parts.

The broken-down nature of the cliffs affords ideal refuge in the heaped-up boulders and talus, and makes control work difficult. While, owing to the use of all holes and burrows on the island by nesting sea-birds over a protracted breeding-season, treatment of burrows has to be confined to the three months November–January.

MECHANICAL CONTROL

During 1927–28, twelve dozen steel-toothed traps in daily use caught 2,415 rabbits—approximately two thirds of the estimated population. In 1928–29, twenty-four dozen traps and 120 wire-noose snares caught 2,908 rabbits, again leaving about one third on the ground. It was found that traps were too slow to catch sufficient numbers in a limited time, and in both winters considerable numbers of wild birds were trapped and so killed. Traps were given up as being inefficient and inhumane. Snares could only work successfully in the few flat and wide areas where rabbits could run fast enough to draw them. Snares fitted with various 'humane' devices were proved too clumsy and conspicuous to be successful. Nets and fence-netting traps were successful only in the flat, open meadows, but were useless in the major portion, which consists of a honey-comb of bird-burrows in rough ground.

Ferrets were unsatisfactory, possibly because for centuries rabbits on Skokholm have known no underground enemies such as the stoat and weasel, and they would not bolt in sufficient numbers.

During the years 1931–36, rabbits were not worth more than 2*d.* or 2½*d.* per lb., and could not have been economically marketed even if they had been caught. They were therefore allowed to increase almost unhindered and soon reached a climax state of about 10,000, the natural increase of summer or its equivalent dying out each winter from natural causes, it is believed chiefly from diseases associated with overcrowding and malnutrition, the common fate of rabbits on many small islands where no human control is attempted.

DISEASE

In the summer of 1936, Sir Charles Martin suggested that the introduction of the virus disease *Myxomatosis cuniculi* might be effective in controlling the population of rabbits. He had found that this malady was 100 per cent fatal to wild rabbits, and in two experiments the disease had exterminated colonies living under natural conditions in an enclosed area of 500 sq. yards in a paddock at Cambridge[1]. The virus of Myxomatosis had been tested upon a variety of domestic animals and wild fauna in the United States, England and Australia and, so far, found to be entirely specific for the European rabbit. The disease produced by it has an incubation period of 5–10 days, at the end of which time the animal becomes feverish and ill, and the eyelids and the nasal mucous membranes become swollen and inflamed. Afterwards a purulent fluid is exuded from the conjunctivæ and nose. Sometimes the mucous membranes at the anal and generative orifices are similarly affected. The exudation from all these situations contains the virus and the infection passes to other animals by contact.

During the last two weeks of September, 83 rabbits were marked, inoculated and released at points scattered over the whole island; 12 of them were afterwards discovered dead in the open. Unfortunately, it was not possible to make this first attempt earlier in the year, so that rabbits infected from those inoculated would not be likely to be found dead before October 4, when the island was abandoned for the winter. It is, therefore, not possible to say to what extent spread of the disease occurred; but when the island was visited in the following spring, there was no trace of the disease in a population which seemed as numerous as ever.

A second attempt was made during the summer of 1937, when 55 rabbits were inoculated with the virus and distributed as widely over the island as before. It was hoped that closer contacts in the breeding season would result in the wider spread of the disease. Both marked and unmarked individuals were found dead of the disease, proving it had spread somewhat; but it appeared to have died out by September, and with no obvious effect on the numbers of the rabbits. A final inoculation of seven rabbits in one warren in the spring of 1938 had the same result—the disease spread but soon died out without exterminating all the members of the warren. Sir Charles Martin had shown that with the strain of virus used intimate contact of healthy and sick animals was required to ensure transmission of the disease, and it may be that the instinctive behaviour of the sick animal in isolating itself and squatting about in the open at the most contagious period was responsible for the failure of the virus as a means of control under natural conditions.

FUMIGATION

Smoke pumped into burrows from a cartridge containing sulphur was found expensive, difficult to handle, and produced a painful death. In 1938 the Universities Federation for Animal Welfare (then the University of London Animal Welfare Society), through Captain C. W. Hume, arranged to make the Skokholm rabbit population the subject of a demonstration of humane rabbit control, using calcium cyanide in the dust form known as 'Cyanogas'. The dust is blown through the passages of warrens by means of hand-pumps, and on contact with the air, gives off the fatal hydrocyanic acid gas. As the dust emerges from exits in a warren, these are blocked so as to ensure concentration of the gas within.

Work was begun in the winter of 1938–39, when tests made on rabbits in rock crevices and shallow holes proved that death occurred within a few seconds, the animals stretching out without excessive movement and without screaming. All the accessible holes were then closed, as so many were bird-holes only. The re-opened holes were treated a fortnight later with the dust, and it was possible to fumigate all holes except those in the steepest parts of the cliffs and among cliff-falls and boulders. When this first treatment was completed, it was estimated that about 90 per cent of the rabbits had been killed. Rabbits from the cliffs seemed to be responsible for many holes afterwards found re-opened inland, and it is probable that had the island been connected with the sea without cliff or boulder 100 per cent extermination would have been achieved.

As it is, after the holes had been gone over for a third time, it was calculated that only about 400 of the original 10,000 (in round maximum figures) rabbits were left, and all of these appeared to be rock-dwellers coming to the top of the island to feed only at night. On this showing, 'Cyanogas' was therefore 96 per cent successful for the island as a whole; excluding the economically untreatable cliff-land, it was still nearer complete success.

Proof of this success was forthcoming in the summer of 1939. White clover appeared where it was always rare and stunted before, grass grew long and luxuriantly, and the absence of rabbit-pellets was remarked. As much as four tons of hay were cut off an acre of the best land; and hay had not been cut since the land was farmed in the last century. The grass continued to grow; one hundred sheep imported in the autumn were found quite inadequate to graze it down and it was eventually beaten down by winter storms.

The residue of rabbits in the cliffs began to breed with rapidity. Normally, under climax conditions, the island rabbits only breed from March until July inclusive. At present they are breeding all the year round as a result of the abundant feed. During the summer of 1939 they spread somewhat inland, helped by the sea-birds, which opened all the blocked holes in that spring. Control has again been carried out this winter by means of 'Cyanogas', and at the moment of writing, the population is again reduced to a residue of rock-dwelling rabbits.

OBITUARIES

Prof. A. G. Högbom

Prof. Arvid Gustaf Högbom, who died on January 19 at the age of eighty-three years, had been a leader in geological work and thought in Sweden for more than half a century, and he came to occupy a dominant position among the geologists of his native land similar to that of his contemporary the late Prof. W. C. Brøgger in Norway (see Nature of April 27, p. 652). A student at Uppsala, Högbom was appointed lecturer there in 1885. In 1891 he joined the staff of the University of Stockholm, but returned to Uppsala in 1896 as professor of geology and mineralogy, occupying the chair until his retirement in 1922; he continued active in investigation and writing until the end. He was born in northern Sweden, most of his field work was carried out there, and he was ever active in promoting the economic development of this sparsely populated region.

Högbom's work was mainly concerned with the Pre-Cambrian and the igneous rocks, the ores, glacial and geomorphological problems, and in latter years with historical and philosophical aspects of the science. Many of the views now widely held regarding Swedish geology were propounded by him, and they had considerable influence in shaping the thought of workers in other lands. The following is a selection only of the subjects on which Högbom made important contributions: the magmatic origin of the iron ores of northern Sweden, the Caledonian overthrusts, the nepheline syenites and associated rocks, the sub-Cambrian peneplain, the Norwegian coastal platform, glacial and fluvio-glacial erosion, the glacial lakes of Sweden, the significance of the clay 'varve', solifluxion, the post-glacial uplift of Scandinavia and the sequence of its climatic changes. Vol. 15, 1916, of the *Bulletin of the Geological Institution of the University of Upsala* was dedicated to him on the occasion of his sixtieth birthday, and the bibliography of 145 items given there bears witness to the remarkable range of his studies.

Högbom was an active participator in international geological congresses, and he will be remembered as a prominent figure at the Congress in Stockholm in 1910. The Geological Society of London honoured him by electing him foreign correspondent in 1911 and foreign member in 1927. L. Hawkes.

Prof. V. I. Sihvonen

One of the first victims of the recent Finnish-Russian War, killed on November 30 during an air raid on Helsinki, was Prof. Väino Ilmari Sihvonen, professor of physical and electro-chemistry in the Tekniska Högskolan of the University of Helsinki. Born in Kangasniemi in 1889, he became a student at Viborg in 1907, a lecturer at the Helsinki Technical High School in 1923, a teacher at the University in 1925 and in 1936, the first holder of the chair of physical and electro-chemistry in the University. He also worked as a student at Dresden, Breslau, Copenhagen and Zurich.

Sihvonen's scientific work was concerned almost exclusively with the oxidation of carbon. Inspired by Langmuir's experiments upon the combustion of carbon filaments in oxygen at low pressure, Sihvonen attempted by similar, more elaborate methods, to gain a deeper insight into the primary mechanism of carbon oxidation. He carried out both static and dynamic experiments, the results of which are published in a large number of papers which have appeared since 1930. In order to explain the relative amounts of carbon monoxide and dioxide formed in these experiments he elaborated a detailed theory which involves the formation of ketone and ketene groupings on the border carbon atoms. His studies included experiments upon the oxidation of graphite and diamond by oxygen in the presence of X-radiation, and the oxidation of carbon by steam and in fused electrolytes. He also made a study of the electrolytic oxidation of tartaric acid and alkali tartrates.

Sihvonen visited Great Britain as recently as 1938 on the occasion of the Faraday Society's general discussion at Bristol upon "Chemical Reactions Involving Solids" when everyone was impressed by his quiet, friendly, unassuming manner. He was a member of the Suomalainen Tiediakatemia and had rendered his country great service in the Finnish war of independence. His tragic death deprives Finland of an outstanding scientific worker and a distinguished teacher.

Mr. J. A. Hobson

John Atkinson Hobson, who died on April 1, was one of the most distinguished among British economists, although he never held any regular academic post and had to wait until the last years of his life for his fellow economists to recognize the importance of his work. Born at Derby on July 6, 1858, Hobson, on leaving Oxford, spent seven years as a schoolmaster, and thereafter for ten years was engaged chiefly in extension lecturing and teaching for the Universities of London and Oxford.

The first book published by Hobson, "The Physiology of Industry" (1889) was written in collaboration with the late A. F. Mummery, well known as business man and Alpine climber; and it contained the germ of his later work. Hobson was already putting forward in 1889 that theory of 'underconsumption' which was for many years to be ridiculed by the great majority of professional economists, though the very great element of truth contained in his theory has in recent years been widely appreciated, and there is a close resemblance at a number of points between his doctrines and those enunciated by Mr. J. M. Keynes in his more recent work. Hobson developed his views in many later books, among which the most important are "The Industrial System" (1909), "The Science of Wealth" (1911) and "Work and Wealth: a Human Valuation" (1914).

In the general approach to economic problems, Hobson was greatly influenced by Ruskin, and he treated economics not as a self-contained science, but rather as a branch of social science as a whole. His works contained much acute criticism of the narrowness of modern orthodox economic theory, and he was continually insisting on the need to approach economic problems from the point of view of human welfare in the broadest sense. Outside the field of economic theory he wrote widely; and at least two of his books have become historical classics. These are "The Evolution of Modern Capitalism" (1894) and "Imperialism" (1902). They remain the most penetrating studies yet written in their respective fields.

During the War of 1914–18, Hobson was actively associated with the Union of Democratic Control, in which he continued to take a lively interest up to the time of his death. He wrote extensively for the *Manchester Guardian*, and was for a long time one of the leading theorists of advanced Liberalism. In his later years, however, he had come to accept a Socialist position, led thereto by the conviction that the capitalist system was essentially restrictive in its working, and was therefore incapable of emancipating itself from the vice of underconsumption.

Hobson, on several occasions, lectured in American universities: indeed, his work was, until quite lately, much better appreciated in the United States than in Great Britain. Personally, he was a man of exceptional charm, with a very lively wit and great capacity for friendship. His series of war-time dialogues, published in the *Nation* during the War of 1914–18 under the name "Lucian", showed how wittily he could write when he chose.

G. D. H. Cole.

Colonel C. T. Green

The death of Colonel Conrad Theodore Green, in his seventy-seventh year, at Birkenhead on April 17, removes one of the best known of Merseyside botanists, for at his own cost and initiative he edited the 1902 and 1933 editions of "The Flora of Liverpool". An active member of many national and local societies, he was a past president of the Liverpool Botanical Society and other societies, and on the executive council of Flora's League he assisted Sir John Abbot-Anderson in the national protection of wild plants by lecturing in numerous parts of the country.

Born at Kirkburton, West Riding, in 1863, Dr. Green obtained a medical practice in Birkenhead in 1887; he was elected to the Linnean Society in 1901; and, after pre-War duty as medical officer in the Territorial Army, he was promoted Colonel, Army Medical Service, in 1915. In 1905 the Chester Society of Natural Science awarded him the Kingsley Medal, for botanical research. He made a long series of microscope slides of micro-fungi attacks upon plants for that Society.

NEWS AND VIEWS

War in the Low Countries

LAST week saw a further extension of the theatre of war in Europe. The Germans, in flagrant defiance of all the rules of international law and courtesy, invaded Holland, Belgium and the Duchy of Luxembourg without any warning whatsoever. The blow was not unexpected, but the manner of its delivery was marked by the callous disregard for all human rights and values which has characterized the Nazi regime and is now seen in its full hideousness. It is not our purpose, even were it possible, to record the progress of the War, but reference must be made from time to time to definite stages of a catastrophe which is affecting the life of every human being in Europe and in many countries outside Europe itself.

As President Roosevelt pointed out in his address on May 10 to the Eighth American Scientific Congress which had just opened in Washington, men of science are not responsible for the misuse of the discoveries of peace to dominate hundreds of millions of people, and there will be universal approbation for the further comment that scientific workers as a whole are prepared to "act together to protect and defend by every means our science, our culture, our freedom, and our civilization". The suppression of individual and intellectual freedom which is being extended through Europe by the hammer-blows of war must be resisted by every means in our power, and the war must be carried to the enemy with the utmost scientific efficiency in the sure hope that, by so doing, we may shorten the period of suffering which is now upon the world.

Advisory Research Council of the Chemical Society

AT the annual general meeting of the Chemical Society held on April 4, the president, Sir Robert Robinson, dealt at some length with the activities of the Advisory Research Council of the Chemical Society which was formed in September 1939, its object being to act as a liaison between chemists engaged in unremunerated research who are seeking guidance as to subjects for investigation of potential value to the national war effort and Government departments or industrial organizations in a position to suggest such topics. Sir Robert said that the response to the suggestions made and invitations issued by the Advisory Research Council has been very gratifying, and that he is sure that the initiative will continue to receive the generous support of the Society's fellows. The situation in regard to scientific research in its application to the War is very different from that of 1914. This is due, partly to the effort made in the War of 1914–18 itself, partly to the intensive work of the intervening years, and in part to the unanticipated course of the present emergency, which has not yet thrown up so many new problems as might have been expected. Nevertheless, there are clear indications that the original work of research chemists will be needed in the present struggle, possibly to a greater extent than in the past, and the relative slowness of the start should deceive nobody in regard to the vitally important part which may be played by the Chemical Society. Certain research committees under Government auspices are already showing a marked tendency to make full use of the Society's facilities in connexion with the longer-range investigations in which they are interested.

It has been laid down by the Advisory Research Council of the Chemical Society that the only subjects to be studied should be such as have a definite relation to the conduct of the War. It is, however, generally agreed that the maintenance of our export trade in a flourishing condition is of the utmost importance, and therefore the Council is prepared to assist the chemical industry so far as lies in its power. Here the attack must be on a broad front and, as it is impossible to spot the winners before the race, there must be losers also. Co-operative effort is essential, and this reflection should console those who are unable to see in what way the suggestions made to them could have any influence on the fortunes of the nation. Fellows may rest assured that more urgent needs will be made known to them when they become apparent to the Council, and all suggestions of a specific nature are welcomed and carefully examined. The Council does not supervise or direct work undertaken at its suggestion, and the results may be used or published in any way that the investigator desires, subject of course to his own private commitments to firms which may have given material assistance or confidential information. Similarly, it can accept no responsibility for the accuracy of the work or for losses sustained or accidents to personnel. As an advisory body the Council is prepared to give any assistance in its power to investigators who wish to ensure that their work is utilized to the full in the national interest. When work is undertaken on behalf of a Government department, this fact is clearly stated, and fellows need not be reminded of the existence of the Official Secrets Act. The Council has no funds at its disposal, but workers on projects suggested by the Council may make application at any time to the Research Fund Committee of the Society. Finally, Sir Robert emphasized that the Council is always available for consultation if any fellow is doubtful of the proper procedure at any stage of his work.

Electrical Invention and Re-Invention

IN the course of his work at the Science Museum, South Kensington, Mr. W. T. O'Dea has had occasion to examine the history of many notable inventions; he gave an account of some of his investigations in a paper bearing the title "Electrical Invention and Re-Invention" read to the Newcomen Society on March 13. His paper contained sections treating of electric lighting, the dynamo, the accumulator, wireless telegraphy, the loud-speaker, television and other subjects. There were instances, he said, of phenomena explored not far enough, or discovered and not fully appreciated. Some inventions, too, lay dormant pending the discovery of a necessary, but ancillary device, or the growth of conditions suitable for their development.

Much interest lay in the story of the dynamo. The first proposal for a self-exciting machine appears to have been made by Sören Hjorth, of Copenhagen, in a patent of 1855. In 1861, another self-exciting machine was proposed by Ányos Jedlik of Budapest, but these proposals led to no development. In 1863–65, Henry Wilde, of Manchester, built machines so nearly self-exciting that it seemed amazing that he should not have continued further. In a paper to the Royal Society in 1866, Wilde wrote that "an indefinitely small amount of magnetism or dynamic electricity is capable of inducing an indefinitely large amount of magnetism", given, of course, the expenditure of mechanical power. In 1866, too, Varley patented a self-exciting machine, but then lost interest in the subject. It was left to Wheatstone and Siemens to describe their self-exciting machines in 1867, but the principle of self-excitation had been discovered and re-discovered three or four times. The paper was illustrated with slides of some of the historic apparatus from the Science Museum.

Water-Power in Durham

A SCHEME for utilizing water-power in Upper Teesdale to generate electricity is put forward by Mr. G. F. Kennedy, who has investigated the matter for the South-West Durham Development Board. According to the *Electrical Review* of May 3, his report has been considered by the Executive Committee of the Board, which has submitted it for Government consideration. The potentialities of the waterfall at Cauldron Snout have been investigated, the object being to facilitate by a cheap supply of electricity the development of industries in Teesdale and Weardale. The report traces the course of the Tees from its source on Cross Fell. Basalt rock forms a natural dam capable of holding 1,250,000 cub. ft. of water, and the overflow from this dam forms the Cauldron Snout cascade into a ravine 135 ft. deep. Mr. Kennedy suggests that as the catchment area extends over 20 square miles a plentiful supply and head of water are assured. It is proposed that the volume should be augmented by the construction of an eight-foot concrete dam, which would increase the natural storage by a further 2¼ million cub. ft., making a total of nearly 4 million cub. ft.

A suggested hydro-electric scheme capable of producing approximately 2 million electric units annually is outlined. At Langdon Beck, Mr. Kennedy suggests that a charge-engineer's house might be built for the control and maintenance of a power station. A pipeline of 28-in. diameter steel pipe 1,200 ft. in length, housed in a concrete duct or tunnel in order to protect it and to avoid spoiling the amenities of the district, is advised, and this, as well as the dam, could be surfaced to resemble the natural contour and appearance of the surrounding terrain. The volume of water thus secured would be able to operate a 21-in. diameter twin-impulse type directly coupled turbine to a 150 kw. alternator. The annual overhead and maintenance costs of the scheme, which would require the services of only one regular attendant as it would be automatically controlled, are calculated to yield a supply at an average cost of a farthing per electric unit.

Transmission Lines on the French Grid

AN article on "Transmission Lines on the French Grid" by D. J. Tynan-Byrd is published in the *Electrical Times* of April 25. The building of the French grid scheme was begun soon after the War of 1914–18, when, owing to the increased industrial and domestic load in different parts of the country, the demand for new generating stations and transmitting stations became urgent. In France, the coalfields lie to the north, and here steam generation to produce electricity is most commonly used. In the southern half of the country, there is abundant water-power available in the Rhône district, in the regions of the French Alps and the Pyrenees, particularly in the spring and summer months when the glaciers begin to melt. The area of France is more than 200,000 square miles, and some regions of dense population possess no facilities for generating electrical energy, while the regions where facilities are abundant often possess few local inhabitants. Hence the policy adopted is to transmit power from areas where it can be generated cheaply to areas where it is in demand.

When a hydro-electric station is built, if no water-storage facilities are available, the station is practically always used for base-load-purposes. If, however, a dam can be constructed, the station will normally be used for peak-load supply. The building of the line is usually arranged and financed by a company which is formed by all the concerns interested, such as power undertakings, railway companies and industrial firms. The Ministry of Public Works, which is equivalent to the Electricity Commissioners in Great Britain, takes a controlling interest in these companies and sees that lines are not built unnecessarily and that they are not duplicated. In some thickly populated areas, where the erection of overhead lines is inadvisable, oil-filled underground cable has been installed. The operation of some of these stations is very ingenious as some of them are 'remote controlled' from larger stations nearby. In some cases, even when the distance of the power station from the distributing area is about ten miles, the whole operation of opening the water valves synchronizing the alternators and finally placing them on load is performed by remote control methods.

The Antarctic *Snow Cruiser*

THE *Engineer* of May 3 gives an illustrated description of the remarkable vehicle which has been constructed for use by the American Antarctic Expedition which sailed from Boston, Mass., on November 15, 1939, in command of Rear-Admiral

R. E. Byrd, U.S.N. The vehicle, called the *Snow Cruiser*, is to be used as a mobile base, and it is reported to be capable of travelling across ice fields, of climbing gradients of 35 per cent, of sliding down them on its steel-ribbed under-floor and of crossing crevasses in the ice 15 ft. wide. The *Snow Cruiser* is more than 55 ft. long, 20 ft. wide and 15 ft. high, and weighs, fully equipped, 33½ tons. It has four pneumatic-tyred wheels 10 ft. in diameter which can be turned independently to various angles, and which can also be retracted into the vehicle. The structure is of steel electrically welded, and the motive power consists of two 150 h.p. oil engines driving electric generators supplying current to the traction motors. In the interior are the living quarters, store-rooms, the engine room, a machine shop and a laboratory, and also tanks for the storage of 2,100 gallons of oil fuel and of nearly 850 gallons of petrol for the aeroplane carried on the back of the vehicle. The *Snow Cruiser* was designed and constructed by the Research Foundation of Armour Institute in Chicago, under the direction of Dr. T. C. Poulter, scientific director of the Foundation, who was second-in-command of the second Byrd expedition.

Puffin Crosses North Atlantic

ONE of the most important results of bird-ringing experiments is the first recovery in North America of a puffin (*Fratercula arctica arctica*) ringed in Europe. This was a specimen ringed by Lord Dumfries as a young bird on St. Kilda on August 10, 1939, and shot at Herring Neck on the north coast of Newfoundland on December 20, 1939 (*British Birds*, March 1940). The instances of European-marked birds traced to North America are very few. The most numerous records are of the kittiwake (*Rissa tridactyla*); specimens marked as young on the Farne Islands, Northumberland, have been recovered in autumn and winter months at Davis Strait, Labrador, and Newfoundland over periods since 1924; another specimen ringed at Khasilov Island, in the Barents Sea, was recovered at Little Fogs Island, Newfoundland. Black-headed gulls (*Larus ridibundus*) ringed at Rossitten, East Prussia, have been recovered in Mexico and the Barbadoes, and there is the celebrated record of Cumberland lapwings (*Vanellus vanellus*) shot in Newfoundland after a gale forced them from their normal migration to Ireland. Previous ringing returns of Scottish puffins have shown no marked westerly migration. Specimens from Northumberland have been recovered at Norway.

Effect of Winter Frosts on Bird-life

IN a lecture to the Hastings and St. Leonards Natural History Society on April 23, Mr. Eric Hardy described the serious effect upon the numbers of insectivorous British birds as a result of the severe frosts during the past winter, when, particularly in the north, vast numbers of thrushes, blackbirds, titmice and other birds were killed by the long absence of food and water. In recounting at length many of his ornithological studies in the north, Mr. Hardy stressed the possible effect of this partial loss of useful insectivorous birds at a time of national food-growing efforts, and the possibilities of increased wireworm damage to cornland, and cabbage white caterpillars to cultivated greens. There is a marked shortage of many of the residential insect-eating birds in woods in the north, although Nature has recovered from the severe winter toll of bird-life more rapidly than was anticipated and it will be interesting to compare the future results with previous hard winters. Nevertheless, there is an urgent need to protect and increase insectivorous birds by providing more nesting and feeding haunts, for example, growing more undergrowth in woods and plantations, and preventing loss of existing bird haunts by river pollution and heath fires.

Canada's Indian Policy

AN interesting review of the circumstances and problems of the Indian population of Canada was given by Mr. Diamond Jenness of the National Museum of Canada, at the recent meeting of the American Association for the Advancement of Science at Columbus, Ohio. The Indian policy of the Canadian Government was framed at a time when to civilize in accordance with the white man's ideals, rather than to conserve, was the aim of liberal and humanitarian administration. Further, it was considered inevitable that such backward peoples would be unable to withstand the difficulties and dangers of contact with civilization and must become extinct. Hence Canadian policy was fusion of the two populations rather than segregation. The Indian was gradually to be absorbed by the white.

Of recent years, however, in Canada, as in other parts of America, the Indian population is increasing; but a more or less successful adaptation to changed conditions, if it has not actually contributed to the increase, as is probable, has certainly averted untoward consequences. This is implied in the comment by Mr. Jenness that the Iroquoians of eastern Canada, "being an agricultural people, . . . were not forced to undergo any sudden revolution". Among the Plains Indians, in the difficult transition from buffalo hunting to growing wheat, the Blackfoot, now the most prosperous, had the advantage of being guided by able and far-sighted chiefs. The Indians of the Pacific coast, both in temperament and economy, have proved less capable of readjustment; but in the Arctic, as might be expected, the Eskimo show themselves well able to hold their own, while the women make excellent wives for the white pioneers who settle on this frontier.

Bureau of American Ethnology, 1938-39

THE major field research with which the Bureau of American Ethnology was associated in the fiscal year 1938–39 (Fifty-sixth Annual Report, 1938–1939, 1940) continued to be that of the United States De Soto Expedition Commission. For the greater part of the year Dr. John R. Swanton was in the field in the interests of the Commission or engaged in the preparation of its report. With various members of the Commission he visited points in North and South Carolina, Georgia, Florida, Missouri, Mississippi, Arkansas and Louisiana. The report has since appeared in a volume of 400 pages.

A joint expedition of the Bureau and the National Geographic Society, under M. W. Stirling, chief of the Bureau, carried out an excavation on a mound site at Tres Zapotes, Vera Cruz, Mexico. Nine major stone monuments were excavated and a large collection of ceramics and figurines obtained. The most important find was a Mayan stone monument inscribed with an initial-series date which apparently records a late Baktan 7 date and is thus among the earliest at present known. The style is closely related to the Tuxtla statuette. This important document has now been deposited in the National Museum, Mexico City. Among other researches, special interest attaches to the investigation of the northern provenience of the Navajo, the largest single-dialect Indian population in the United States, numbering some 50,000 souls, inhabiting Arizona and New Mexico. Their language is an aberrant form of Western Apache, belonging to a group of which the northern origin is patent and traceable as closely related to Athapascan tongues occupying the interior of Alaska and western Canada. Dr. F. H. H. Roberts, continuing his researches on the character and distribution of Folsom man in the period under review, has traced this early prehistoric culture so far north as Saskatchewan, along the postulated migration route of peoples coming from Asia into the New World.

Canadian Polar Year Expeditions, 1932–33

THE Second International Polar Year, 1932–33, during which many nations joined in the simultaneous recording of meteorological, geomagnetic and auroral data in the polar and other regions of the globe, belonged to an epoch when the nations of Europe and elsewhere could still devote money and energy to a great co-operative scientific enterprise. Though receding in memory, some of its fruits still remain ungarnered; this has now been accomplished, for the share of Canada in the magnetic and auroral part of that enterprise, by the publication of volume 2 of the report of the three Canadian expeditions (volume 1 deals with the meteorological results). A new magnetic observatory was set up for the year at Chesterfield Inlet (63·3° N., 90·7° W.), which is not far from the north magnetic pole—the magnetic needle at Chesterfield Inlet departs from the vertical by only 3·6°—and is also near the auroral zone, the centre of which is the pole of the earth's magnetic axis. In addition, the equipment of the Meanook Observatory, set up in 1916, was improved for the Polar Year work: Meanook (54·6° N., 113·3° W.) is also in a high magnetic latitude.

The report gives very full details, on an internationally arranged plan, of the magnetic observations made during the year at these two stations; the tables cover more than eighty quarto pages closely printed; they are likely to prove, for many years, valuable raw material for theoretical studies, as was the case with the records of the first Polar Year (1882–83), the value of which is still not exhausted. In addition, the report gives particulars of earth current observations at Chesterfield Inlet, and of magnetic measurements at field stations visited from Chesterfield; together with more than fifty pages of records and discussion of auroral observations made at Saskatoon and at Chesterfield Inlet; this part of the report is illustrated by many line diagrams and photographs of auroras. Height measurements were made by simultaneous photography from two stations separated by 112 km.; they showed that the most usual height of the lower edge of the auroras measured was about 100 km., as in Norway. Auroras extending below 80 km. were observed on at least one occasion.

Robert Mond Bequest to the British Museum

A FURTHER instalment of descriptive notes on outstanding objects in the collection of antiquities bequeathed to the British Museum by the late Sir Robert Mond (*Brit. Mus. Quarterly*, 14, 1; 1940) deals with funerary portraits of the Roman period from the Fayyum, an example of a theriomorphic vase possibly of the middle predynastic period in the form of a frog and two small granite heads, of which the smaller presents the remarkable and unusual feature that the eyes are shut, so that the effect is that of the portrait of a dead person, while the contour of the main features resembles that of a skeleton. It seems to be without parallel, and no opinion can be expressed as to its age without the greatest reserve. Much interest is attached to a small hollow cylinder of black and white porphyritic rock, which belongs to a class of objects of which the use has not yet been determined satisfactorily. At one time they were thought to be mace heads, though secure hafting seems an impossibility; but recent discoveries at Wadi Halfa, in which they were found in association with other weapons and in some burials with two fingers of the right hand, have led to the suggestion that they were archers' looses, and in their use resembled the Mongolian ring. All datable examples are from sites occupied by the people to whom archæologists apply the term the *X*-group, who occupied Upper and Lower Nubia from the third to the sixth centuries A.D., variously identified with the Blemmyer of the Eastern Desert, the Noubades, a mixed race of negroid and Meroitic elements, and the Nobatae, who are alleged by Procopius to have formed a buffer State between the Roman frontier at the First Cataract and the southern barbarian tribes.

Taxonomy in the Amaryllidaceæ

THE present trend towards specialization makes possible, and indeed necessary, a detailed volume such as *Herbertia*, the year-book of the American Amaryllis Society. The editor, Dr. Hamilton P. Traub, has brought together in the sixth book, for 1939, a collection of knowledge upon all matters pertaining to the horticulturally valuable members of the Amaryllidaceæ. There are the usual descriptions of exhibitions and garden culture, of grouping and floral artistry; there is a dedication of the present volume to the Union of South Africa; there are personal references, mainly to the work of South African investigators and to the Herbert medallists of 1939, among whom is Dr. J. Hutchinson. There are also several short papers of scientific interest, but the outstanding contribution of the volume is to the science of taxonomy.

"A Review of the Genus Cyrtanthus" by Dr. R. A. Dyer contains detailed descriptions of forty-four species in the genus which occur in the eastern and southern regions of South Africa. Three species are described for the first time, namely, *C. falcatus*, *C. attenuatus* and *C. bicolor*. Dr. H. P. Traub and J. C. Th. Uphof have also made a further revision of the genus Amaryllis, and publish a key to the species, of which seventy-seven are now recognized. Other new species described in the volume are *Amaryllis Kromerii*, *Zephyranthes insularum* and *Z. Plumierii*, the two last-mentioned being described by H. Harold Hume from the West Indies. A cytological confirmation of taxonomy in the genus Cooperia is furnished by Walter S. Flory, who shows by means of chromosome counts that the recently discovered *C. Traubii* is distinct from the earlier *C. Drummondii* and *C. pedunculata*. A useful correlation between rainfall and the distribution of Amaryllids is drawn by Frances M. Leighton, who shows that these plants prefer the moister parts of South Africa, with equal distribution of the rainfall between summer and winter. They will, nevertheless, grow in quite arid regions, but in dry summers the plants lose their leaves before flowering.

Infra-Red Drying

IN the spectrum the radiations which have a wavelength greater than 7600 A. include those that produce a maximum sensation of heat. The *Electrical World* of New York gives an important practical application of this scientific fact which has effected appreciable economies in drying the paint of letters made for advertising signs, which in many cases have to withstand rough usage. In a test the average time of air-drying took about twelve hours, occupying valuable space and giving time for dust to collect on the surface of the product and so spoiling its finished appearance. With the new arrangements, the sprayed letters are placed on an endless chain, travelling in one direction on the upper level and in the other on the lower level before being dumped into a bin. During this period, which lasts only 7½ minutes, the letters are exposed to the rays from twenty-four 250-watt infra-red lamps staggered at 10-in. centres. An earlier use of infra-red rays was made at Ford's works in Ohio. This method has apparently been successful; and if suitably modified would be useful in other practical applications.

Accidental Deaths in Old Age

ACCORDING to an editorial in the September issue of the *Statistical Bulletin*, issued by the Metropolitan Life Insurance Company of New York, the 7,500,000 persons of 65 years and more form only 6 per cent of the total population of the United States, but fully a quarter of the annual fatal accidents in that country occur in persons of that age. This excessive mortality is found both in men and women, but is relatively higher in women. Falls are by far the most frequent causes of fatal accidents in old people, and account for about 15,000 such deaths annually in the United States. The commonest types are falls on floors, stairs and in the street, and relatively few deaths are due to falls from high places. Motors cause the death of about 5,500 old persons, about two thirds of the deaths being due to accidents in which vehicles strike pedestrians. Accidental burns (apart from conflagrations) account for 1,100 deaths every year at this age, a large number of the deaths being caused by clothing catching fire at stoves and grates. Deaths from illuminating gas poisoning are frequent in elderly persons, probably because they do not detect the smell of escaping gas so well as younger persons, and are less likely to recover from carbon monoxide poisoning. The writer expresses the hope that the education of youth to-day in safe ways of living will be of value not only at the present time but will also benefit the aged of the future.

The Imperial Cancer Research Fund

THE thirty-seventh annual report (1938–40) of the Imperial Cancer Research Fund was presented to the annual meeting of the Governors on April 17. Prof. H. R. Dean, Prof. H. W. Florey, Prof. C. A. Lovatt Evans, and Prof. J. Beattie have been appointed members of the council. Mr. Hugh Lett gave a brief historical account of the work of the Fund since its foundation. Two events of importance to the Fund have occurred since the publication of the last report: a royal charter of incorporation was granted on August 29, 1939, and the new laboratories at Mill Hill were opened on June 27 of the same year. The director, Dr. W. E. Gye, summarizes in the report the researches that have been conducted in the Fund's laboratories. These include work by Dr. R. J. Ludford on the comparative reactions of normal and malignant cells in tissue culture to some chemotherapeutic compounds. A Polish State scholar, Dr. Dmochowski, has investigated antigenic differences between normal and malignant cells. His results demonstrate that there is a fundamental difference between transplanted tumours and spontaneous tumours that may arise in an animal. In the former the malignant cells are introduced and are 'foreign' to the animal, and give rise to reactions which are absent in animals bearing spontaneous tumours, in which the tumour cells are part of the animal's body and are not 'foreign'.

The South-West Essex Technical College

DR. LOWERY, principal of the South-West Essex Technical College and School of Art, has presented to the Governors the first annual report, for the session 1938–39. The College replaces former technical institutes at Leyton and Walthamstow, together with a commercial school for girls at the same place and a school of art at Leyton, and embodies a comprehensive scheme for the development of technical education in the county. When the Principal took over duty in April 1938, the buildings were far from complete and the workshops and laboratories only outlined. These handicaps were well overcome; besides the teaching staffs transferred, many new heads of departments and lecturers were appointed; and at present the full-time staff numbers 82 with 180 part-time instructors. The number of students for the session reached 6,842. Association with the four institutes mentioned and various junior schools has been achieved without a hitch.

We notice a general building course, three foreign language clubs which have run successfully on self-governing lines, and classes on milk technology, bee-keeping and glass-blowing. Biology on Saturday mornings has attracted local teachers, who have maintained a high standard of work and steady attendance. The success of the College and the demands for its teaching are a credit to all concerned. It may well be a model for a substantial advance in education elsewhere.

Progress in Education

EDUCATION in the United States is well served by several periodicals. The issue for February last of *School Life*, the official organ of the U.S. Office of Education, is well illustrated and full of live discussion of controversial issues, while it illustrates the enterprise of educational authorities. The science department of Dover High School in Ohio has leased twenty-five acres of potential flood land which are to be used as a field laboratory for the study of ecology and the management of streams and ponds. It is suggested that the Decennial Census, which is due in April, might be discussed in schools, as it has a very wide scope and will include housing for the first time. *School and Society*, February 17, begins with a good article on "The Teacher Pupil Relationship in a Democracy" and ends with a striking one on "Vocabulary and Success in College". Vocabulary and style are, in fact, of great importance for success in life. Max Müller was not well informed when he put down the words used in a country parish as less than 300; but the rustic world, which has its own expert information to give, is still hampered by its incoherence, and education should be always enlarging the effective use of language. On the elementary side, it is to cost Great Britain, according to the latest yearly estimate, well over 36 million sterling. Forty years since, men of science were below the educated standard in books and journalism; now they are distinguished for good writing, which is appreciated by the general public. This is particularly needed in science, since discoveries are exaggerated and misstated by fluent 'stunt' writers who popularize without adequate knowledge.

Announcements

DR. W. SUCKSMITH, lecturer in physics in the University of Bristol, has been appointed to the chair of physics in the University of Sheffield, in succession to Prof. S. R. Milner, who is retiring at the end of the present session.

THE following appointments and promotions in the Colonial Service have recently been made: D. C. Edwards, agricultural officer, senior agricultural officer, Kenya; E. T. Holmes, senior agricultural officer, Nigeria, senior agricultural officer, Sierra Leone; G. W. Nye, senior botanist, deputy director of agriculture, Uganda; A. H. W. Weir, conservator of forests, deputy chief conservator of forests, Nigeria.

IN commemoration of the centenary of the foundation of King's College Hospital a tablet was unveiled on April 17 at Strand House, Portugal Street, London, which showed the site occupied by the hospital from 1839 until 1913.

THE Rockefeller Foundation has made a grant of some £200,000 to Prof. E. O. Lawrence for the construction at the University of California of a cyclotron of 184 in. diameter. The total weight of this apparatus will be about 5,000 tons and it will take about three years to build. Such a machine is expected to produce deuterons of 10^8 volts energy.

DR. PHILIP E. SMITH, professor of anatomy at the College of Physicians and Surgeons, Columbia University, was elected president of the American Association of Anatomists at the fifty-sixth annual convention held at Louisville, Kentucky, on March 21.

To encourage the preparation of papers by students of fuel technology, the Council of the Institute of Fuel has decided to make an annual award of a medal, together with a prize consisting of books and/or instruments to the value of £5. A copy of the rules governing the award can be obtained from the Secretary, Institute of Fuel, 30 Bramham Gardens, London, S.W.5.

THE Egypt Exploration Society, of 2 Hinde Street, Manchester Square, London, W.1, and 1450 Broadway, New York, announces that on September 1 it will publish in two volumes "Temples of Armant" by Sir Robert Mond and Oliver H. Myers. Lady Mond has generously made it possible to finish the work of the Mond Expedition in the manner originally contemplated, and the last three years work is being published in two memoirs, "Temples of Armant, a Preliminary Survey", and "Cemeteries of Armant II and a Saharan Culture". Each work will be published in two volumes, one of text and one of plates (some of which will be coloured), in the same style as "Cemeteries of Armant I".

REFERENCE was made in NATURE of May 4, p. 701, to the amalgamation under the style of Newton and Co., Ltd., of two well-known firms of the name of Newton. It should have been stated that the combined business is now being carried on at 72 Wigmore Street, London, W.1.

ERRATUM.—In the letter entitled "Rhythmical Impedance Changes in the Trout's Egg" in NATURE, May 11, p. 744, line 11, for "sodium nitride" read "sodium azide".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

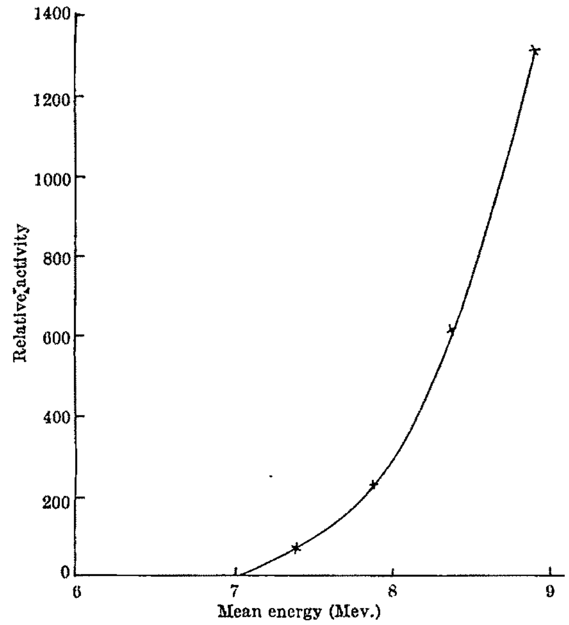
NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 784. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

A New Type of Disintegration Produced by Deuterons

IN a previous communication from this laboratory, Krishnan and Gant[1] reported the formation of ^{106}Ag when silver was bombarded with 9 Mev. deuterons. It appears that this reaction can only be explained by

$$^{107}\text{Ag}\ (d - d, n) \text{ or } (d - p, 2n)\ ^{106}\text{Ag}.$$

Since it is well known that ^{62}Cu can be produced by certain methods which also yield ^{106}Ag (namely, $n - 2n$, $\gamma - n$), it was therefore considered that deuteron bombardment of copper might also produce ^{62}Cu. We have bombarded pure copper foil with a few microampere-minutes of 9 Mev. deuterons from the Cavendish cyclotron. The copper fraction was chemically separated from the bombarded sample and its positron activity was examined with a Geiger-Müller counter (the magnetic field used to resolve the positrons being adjusted so that the positrons from ^{64}Cu were excluded). A single positron activity of energy more than 2 Mev. with a half-life of 10·5 minutes was observed. This would appear to be due to the well-known ^{62}Cu[2]. Excitation function measurements were made by exposing a pile of copper foils (11·4 mgm./sq. cm.) to the deuteron beam and then measuring the activities after chemical separation as above. The accompanying energy-yield curve was obtained.



The threshold for the production of this radio-element seems to be at about 7 Mev. The nature of the curve clearly indicates that the effect cannot be due to the neutron or γ-ray background, and it would seem to explain why the effect was not observed earlier, in that previous experimenters did not use deuterons of more than 8 Mev. energy.

Further experiments were made in an attempt to decide whether the reaction was $(d - d, n)$ or $(d - p, 2n)$. If the latter alternative be correct, the $(d - p)$ reaction should be observed to decrease as the $(d - p, 2n)$ reaction increases, these two being opposing reactions. The excitation function for the formation of ^{64}Cu (12·8 hr.) by deuteron bombardment of copper $[(d - p)$ reaction] was measured (this was first done by A. G. Ward in this laboratory and later confirmed by us), and it was observed that the yield from this reaction decreased above 8 Mev. This result would seem to show that in the formation of ^{62}Cu the $(d - p, 2n)$ reaction is more probable than the $(d - d, n)$ reaction.

R. S. KRISHNAN.
T. E. BANKS.

Cavendish Laboratory,
Cambridge.

Calculations on the Energies of Hydrocarbons

WE have made a number of calculations on the energies of various hydrocarbons and have also obtained related properties such as the internuclear distances in the ground and simple excited states, the heats of formation and the approximate wave-length of certain absorption bands. Incidentally, an estimate of the heat of sublimation of carbon has been made which is probably as reliable as any other value hitherto given.

The energy of the most stable state of benzene may be written $6H + 6S - 0{\cdot}4J$, while the energy of the nearest excited singlet state is $6H + 6S - 3{\cdot}0J$, where H is the energy of the carbon-hydrogen bond, S and J are functions defined by Lloyd and Penney[1]. The shape of the excited state is found to be regular, with the C–C link about 1·44 A. in length. The experimental value of the 'breathing frequency' in this state is 920 cm.$^{-1}$. The calculated value is a little more than 900 cm.$^{-1}$, the exact value depending on the type of potential function assumed for the double bond and the normal 'benzene' bond (namely, parabolic law, Morse function, etc.). The energy difference between the two states is roughly $2{\cdot}6J$, where J has its value at the normal ring distance, and is therefore 1·85 e.v. Hence the absorption band corresponding to the transition from one state to the other is calculated to be about 39,000 cm.$^{-1}$—almost exactly the observed value. When suitable refinements are made in the theory, the agreement with experiment is still almost exact. This part of our work may be regarded as an extension of a theory of the origin of the absorption bands of benzene proposed by Sklar[2].

Similar calculations on butadiene show that the central C–C link has a length 1·42 A. in the excited state, compared with 1·43 A. in the ground state, and the outer links have lengths 1·61 A., compared with 1·34 A. in the ground state. The energy difference between the two states is 45,000 cm.$^{-1}$, compared with the experimental value 48,000 cm.$^{-1}$. For this molecule, it will be noticed, the internuclear distances in the two states are very different, and as a result, the band in the fluorescent spectrum arising from the transition from one to the other should show considerable vibrational structure.

Calculations on more complicated polyenes have also been made, with results similar to those quoted for butadiene.

The theory employs only the double bond and benzene bond energies and force constants. Now the force constants are known within a few per cent, and in any event their importance in the theory is only subsidiary. Thus the only uncertainty is that arising from the unknown value of the heat of sublimation of carbon, placed by various observers between 130 and 170 kcal./mol. Pauling[3] adopts the latter value. Support for his view may be obtained as follows. Suppose that the heat of sublimation is changed to $(170 - \Delta)$ kcal./mol. Then the calculated value of the energy of the absorption band of benzene mentioned above is decreased roughly by $8\Delta/7$. Thus if $\Delta = 40$, the calculated energy of the band is changed from 111 kcal./mol. to 65 kcal./mol., the observed value being 110. Similarly, the agreement between theory and experiment for butadiene is completely spoiled. We conclude that the heat of sublimation of carbon is 170 kcal./mol., with a possible error of 10 kcal./mol.

Full details will be published later.

Structure of the OD Bands of Heavy Water

BANDS due to the OD molecule have been photographed with a large quartz Littrow and a 10-ft. concave grating spectrograph by using discharges through vapour of heavy water of a high degree (99·6 per cent) of purity. The bands at λ2872 and λ2916 have been measured. They correspond to the (1, 0) and (2, 1) bands of OH with heads at λ2811 and λ2875 due to the electronic transition $^2\Sigma^+ \rightarrow {}^2\pi_{\text{inv}}$. With the aid of the rotational differences derived from the six main *P*, *Q* and *R* branches the mean values of the constants for the band λ2872 are found to be (in cm.$^{-1}$) as follow:

$$B'_v = 8{\cdot}736 \quad ; \quad D'_v = 0{\cdot}548 \times 10^{-3}$$
$$B''_v = 9{\cdot}870 \quad ; \quad D''_v = 0{\cdot}420 \times 10^{-3}$$

The values B'_v and B'' are in good agreement with those calculated from the corresponding constants of the OH molecule using the mass ratio, $P^2 = 0{\cdot}5301$ (^{1}H = 1·0081 and ^{2}H = 2·0142) for the two isotopic molecules OH and OD. The wave numbers of R_1 (1) and Q_1 (1) are 34796·9 and 34761·6 cm.$^{-1}$ respectively.

Full details of the structure will be published elsewhere.

The Generalized Kaleidoscope

PROF. H. S. M. COXETER, in his recent admirable essay[1] on polyhedra, has brought the generalized kaleidoscope to the notice of a wider public. In the accounts of this apparatus which I have seen, there is no reference to those cases in which the angle between two of the mirrors is 120°. The trihedral examples, though interesting, are perhaps of less importance than the case described below.

It is said to have been proved that a kaleidoscope cannot have more than six mirrors; it is, however, possible to have one with eight arranged in a manner suggested by the faces of the rhombic dodecahedron. Take four mirrors the shape of congruent isosceles triangles with the angle at the vertex equal to 70° 32′, and arrange them so that they form the slant faces of a pyramid on a square base. (The images of a point-object at the centre of the base, including the object itself, form the vertices of an octahedron). Taking another set of four mirrors, arranged as before, and bringing the two sets together base to base, an octahedron of mirrors is obtained, the dihedral angles of which are 120° and 90°. The images of a point-object inside it, together with the object itself, form the vertices of a solid tessellation of cuboctahedra and octahedra.

Carbohydrate Metabolism of Tumours

RECENT correspondence by Drs. Boyland and Dickens in NATURE has raised once again the question of the existence of an abnormal carbohydrate metabolism of tumours.

Dr. Dickens[1] maintains that, whilst neither aerobic glycolysis alone nor in combination with a low respiratory quotient is "in the strictest sense specific for tumours, . . . nevertheless, the association in tumour metabolism of relatively high aerobic and anaerobic glycolysis with the lowered respiratory quotient is such a constant one that to dismiss it is to discard as unimportant the most characteristic of established biochemical peculiarities of tumour tissue". We agree with Dr. Dickens that this type of metabolism is very common in tumours, but whereas Dr. Dickens (whose opinion on this matter is still shared by many other workers) considers it as the most characteristic of established biochemical peculiarities of tumour tissue, we feel that such features of carbohydrate metabolism, as stressed by Warburg, Dickens and others, are in no sense peculiar to tumour growth, and have no significance in the elucidation of the tumour problem.

In his communication to NATURE, Dr. Dickens brings forward the following arguments in support of his case: (*a*) Practically all tumours have a strong aerobic glycolysis and a low respiratory quotient; (*b*) normal tissues, with few exceptions, do not possess this type of metabolism; (*c*) in the experimental production of hepatomata, the liver cells acquire the type of metabolic activity characteristic of malignant tissue; and (*d*) when muscle is replaced by malignant sarcoma, a great increase of glycolysis occurs.

These arguments would seem untenable on the following grounds:

The tumours, the metabolism of which has so far been investigated, are derived from tissues which *normally* glycolyse aerobically (for example, from skin and intestinal epithelium and fibroblasts). On the other hand, a number of spontaneous tumours have been found to be entirely free from aerobic glycolysis[2].

With regard to the metabolism of normal tissues, to say that, with few exceptions, they do not possess this type of metabolism, is erroneous. On the contrary, as Boyland points out[3], ". . . most body tissues (with some exceptions such as kidney cortex, spleen, ovary and lung) which have been carefully examined appear to have some aerobic glycolysis". Indeed, several normal tissues glycolyse more strongly than many malignant tumours. The argument that the aerobic glycolysis of certain normal tissues is due to a hypothetical 'damage' resulting from the use of an unsuitable medium has been disproved in the case of kidney medulla by Dickens himself (in collaboration with Weil-Malherbe[4]). In the case of fibroblasts in tissue culture, the argument is all the more unreasonable, since the metabolic values are obtained under conditions which are probably far more physiological than with the accepted slice technique. To consider all non-glycolysing normal tissues and glycolysing tumours as the rule, and all glycolysing normal tissues and non-glycolysing tumours as exceptions, is clearly unreasonable.

The citation as evidence of the metabolism of hepatomata is of doubtful value, since normal liver itself glycolyses both aerobically and anaerobically to a variable extent, depending on the state of nutrition of the organ. In a hepatoma, the aerobic glycolysis may be several times that of the average values of normal liver[5], but hepatomata with little or no aerobic glycolysis have also been reported[6]. In any event, many investigators (including Dr. Dickens) have long since abandoned the idea that aerobic glycolysis is, in itself, peculiar to tumours. According to the current theory, it is only aerobic glycolysis together with a low respiratory quotient which is taken as a metabolic defect characteristic of tumour growth. So far as we know, no one has yet measured the respiratory quotient of hepatomata, and it is difficult to see what significance can be expected from such measurements, since *normal* liver is known to have a low respiratory quotient[7].

Finally, as regards the great increase in glycolysis when "muscle is replaced by malignant sarcoma", this is the most misleading argument of all, since the sarcoma in question (Rous I) is of connective tissue origin (macrophage[8] or fibroblast[9]), and is not derived from the muscle "which it replaces".

Most investigators who consider aerobic glycolysis in combination with a low respiratory quotient as significant features of tumour metabolism, base their arguments (1) on a comparison between the metabolism of tumours derived from skin or intestinal epithelium or connective tissue with such normal tissues as pancreas, liver, spleen, testis, etc., instead of with the normal tissues from which these tumours happen to be derived, and (2) on the hypothetical assumption that the glycolysis of most normal tissues is due to an artificially induced damage.

In an attempt to avoid both these sources of error, we have carried out a comparative study of the metabolism of normal rabbit skin epithelium (a tissue evidently resistant to damage) and the Shope papilloma derived from it. We found[10,11] that the values for respiration, aerobic and anaerobic glycolysis and respiratory quotient for the two were almost identical, and similar to many of the values for skin carcinoma quoted in the literature.

From these observations and from the work recorded in the literature on the glycolysis of normal mucous membrane and fibroblasts, we draw the conclusion that, *when a tumour is compared with the tissue from which it is derived*, there are no characteristic differences or peculiarities between the carbohydrate metabolism of the two.

[11] Berenblum, I., Chain, E., and Heatley, N. G., *Amer. J. Cancer*, 38, 367 (1940).

WE agree with Berenblum, Chain and Heatley, and with Boyland[1], that high aerobic and anaerobic glycolysis and low respiratory quotient, while very common properties of tumour tissue, are not specific. In fact, we have in hand additional work to be published soon which shows that intestinal mucosa[2] possesses very active aerobic and anaerobic glycolysis combined with a low respiratory quotient.

On the other hand, these authors maintain that the tumours so far studied which have high aerobic glycolysis and low respiratory quotient have arisen from normal tissue which itself has this type of metabolism. The present evidence for and against this view does not seem to us conclusive. Only two examples are yet known in which such a strict comparison is possible; for in our opinion the value for this purpose of measurements on cultured tissue-cells, growing under conditions which are certainly unphysiological, is very doubtful.

The first example is the hepatoma, to which Berenblum *et al.* take exception on the grounds that aerobic glycolysis may sometimes be lacking in hepatomata, and that normal liver has variable and often considerable aerobic glycolysis. Both in our own experience, however, and in the recorded values, we have always found the aerobic glycolysis of liver to be small compared with its respiration, especially when it is remembered that the often large formation of acetone bodies by this tissue must be taken into account. The second example is the transformation of skin epithelium into Shope papilloma, studied by Berenblum, Chain and Heatley[3]. Some experimental data are not detailed in this paper, such as the medium used, the number of observations and the consistency of the results; also it is not stated if normal tissues give the same values of aerobic glycolysis and respiratory quotient in the minute pieces used as they do in the usual larger-scale experiments. The purity of the papilloma tissue used for comparison with 100 per cent pure epithelium and the stage of malignancy arrived at are also desirable data. However, in the one example given, there was no change of metabolism other than a slight general lowering of all the figures, including respiratory quotient, when a tumour had resulted.

In our opinion, these two cases counterbalance one another, and no general conclusion can as yet be drawn as to the occurrence of an alteration of metabolism in the development of cancer.

Chemical Estimation of Vitamin B_6 in Foods by Means of the Diazo Reaction and the Phenol Reagent

The recent investigations of Kuhn and his co-workers[1] and Harris and Folkers[2] have shown that vitamin B_6 is 2-methyl-3 hydroxy-4 : 5 di(hydroxy-methyl)-pyridine. It contains a hydroxy group in the β-position of the pyridine ring, which gives the characteristic red coloration of true aromatic phenols with ferric chloride. The vitamin also gives colour reactions with diazotized aromatic amines and the phenol reagent of Folin and Ciocalteu[3].

A method has been developed for the estimation of the vitamin in biological materials using diazotized sulphanilic acid or the phenol reagent. Since these reagents are not specific for vitamin B_6, it is necessary to remove all interfering substances before colorimetric estimations can be carried out. By the procedure outlined below it has been found possible to obtain values for the vitamin B_6 content of various foods which appear to correspond approximately to those obtained by other workers using biological methods

A suitable quantity (2–50 gm. containing 10–20 rat units of vitamin B_6[4]) of the finely minced or powdered test material was digested with pepsin for twenty-four hours. Protein and its derivatives were removed by tungstic acid. Purine, pyrimidine and imidazole bases were precipitated with silver nitrate and barium hydroxide and the excess silver removed. The solution was adjusted to pH 1–2 and the vitamin B_6 present was adsorbed on clarite (2 gm.). The vitamin was eluted from the clarite with hot barium hydroxide and the silver precipitation was repeated. The solution was then adjusted to pH 6, concentrated to 25 ml., and treated with sodium nitrite and acetic acid for 15 minutes to destroy any amino group that might be present. After bringing the pH to 7, the solution was filtered and made up to 50 ml. 10 ml. aliquots were treated with diazotized sulphanilic acid and the azo colour formed estimated colorimetrically by comparison against a standard of 20 μgm. of pure vitamin B_6 treated in the same way. The method is highly sensitive. 10 μgm. of vitamin B_6 is easily estimated and the colour obtained is proportional in intensity to the amount of vitamin present. The values for fifteen foodstuffs are given in the accompanying table.

VITAMIN B_6 CONTENT OF VARIOUS FOODSTUFFS

Foodstuff	*Vitamin B* *μgm./gm.*
Yeast, dried (brewer's)	54·0
Yeast, dried (brewer's) (autoclaved at pH 9·4)	53·0
Rice polishings	13·4
Liver, sheep	13·4
Muscle, sheep	4·5
Milk, cow's	1·7
Maize, yellow, whole	7·1
Wheat, whole	7·6
Cholam (*Sorghum vulgare*)	8·0
Rice, husked	6·6
Rice, highly milled, raw	3·0
Soya bean	8·0
Beetroot	1·3
Cabbage	3·1
Plantain, ripe	1·3

Known amounts of vitamin B_6 were added to weighed quantities of foodstuffs and the recovery was good in all cases, ranging from 70 to 100 per cent

The method described is applicable to all types of foodstuffs. It is probable that in some cases it may be abbreviated. For example, treatment with nitrous acid has been found to be unnecessary in the case of yeast. Possibly the second silver precipitation is not always necessary A variety of different phenolic reagents may be used and many modifications in detail are possible. For example, with yeast and potatoes comparable values have been obtained using diazotized sulphanilic acid and p-nitroaniline and the phenol reagent, nitrous acid treatment being omitted.

A fuller account of these investigations will be published in the *Indian Journal of Medical Research*

Liberation of Potassium from Muscle by Acetylcholine and Muscle Contraction and its Absence after Adrenalectomy

Cicardo and Moglia recently announced in Nature[1] that, after injecting acetylcholine into the sciatic artery of a toad, "the contracture of the muscles is accompanied by an increase in the concentration of potassium in the liquid flowing from the vein".

In a paper presented to the Swiss Physiological Society on January 27[2], we announced a similar result in four normal cats. An injection of 5–40 acetylcholine was made into the femoral artery towards the muscle, and all the venous blood coming from the leg muscles was collected.

There was a great increase of plasma potassium, from 15 mgm. per cent without injection of acetylcholine, to 25 mgm. per cent or more after the injection. The liberation of potassium ceased a few seconds after the injection. The total quantity of potassium liberated was about 0·5 mgm., most of which came from the gastrocnemius muscle.

In confirmation of numerous previous experiments, we were also able to show, on the same preparation, that the plasma potassium is also raised during contraction of the gastrocnemius caused by electrical stimulation of the sciatic nerve.

In nineteen experiments on twelve cats, the plasma potassium increased from 16·1 mgm. per cent to 28·2 mgm. per cent. The gastrocnemius (weighing about 30 gm.) liberated about 1·5 mgm. of potassium during 4,000 gm. cm. work per minute. This reaction also ceased immediately after the end of the contraction, while lactic acid production continued for some minutes.

We were especially interested, in these experiments, in their bearing on the question of muscle metabolism after adrenalectomy.

As we have shown in previous experiments[3], there is a close connexion between carbohydrate and potassium metabolism which is disturbed after adrenalectomy. We therefore repeated the above experiments on adrenalectomized cats, and were able to show that after injection of acetylcholine into the muscle artery, no potassium whatever was liberated (nine experiments on four cats).

Similarly, after electrical stimulation of the sciatic nerve, the plasma from the muscles of adrenalectomized cats showed no (or only a minimal) increase of potassium (eleven experiments on five cats).

The plasma potassium of these animals, on the second to fifth day after the second adrenalectomy, was raised as usual, but did not change after stimulation. The total quantity of potassium liberated for 4000 gm. cm. work per minute was only 0·2 mgm., which is an almost negligible quantity.

Since potassium plays a part in carbohydrate metabolism, we believe that these changes in plasma potassium are connected with the absence of glycogen re-synthesis after adrenalectomy.

The detailed report of these experiments will be published later.

Function of Chlorocruorin in Sabella and of Hæmoglobin in Lumbricus

A number of invertebrate animals possess blood pigments which are generally assumed to be respiratory, although only in a few instances has a respiratory function been demonstrated experimentally. One or more of three functions are imputed to these pigments: (*a*) they may act like hæmoglobin in ourselves, as a transporter of oxygen at all times; (*b*) they may come into action as oxygen transporters only when oxygen is deficient in the outside world, there normally being enough of the gas in simple solution in the blood for the restricted wants of the relatively sluggish animal; (*c*) they may serve as a reservoir of oxygen to be drawn upon during temporary shortage of the gas in the environment.

Among the invertebrates, function (*a*) has hitherto been demonstrated only in a single case, namely, in Tubifex. When the hæmoglobin of this freshwater oligochæte worm is put out of action with carbon monoxide, the animal consumes less oxygen at atmospheric and all lower oxygen pressures[1].

Because the hæmoglobin of the polychæte worm Arenicola has a very low loading tension (oxygen pressure for 95 per cent oxyhæmoglobin)[2] and can therefore take up oxygen from water in which the pressure of the gas is low, function (*b*) has been suggested for it[3]. But this suggestion lacks experimental proof, and if the oxygen pressure in the respiring tissues were close to zero, the oxyhæmoglobin, in spite of its low unloading tension (oxygen pressure for 50 per cent oxyhæmoglobin), would still give up its oxygen to these tissues even when the worms are in air-saturated water. Experimental evidence has, however, been adduced that function (*b*) is exhibited by the hæmoglobin in the blood of the earthworm[4,5], but work on Lumbricus now completed in this laboratory by Dr. M. L. Johnson has proved that this is not so and that the blood pigment of the earthworm has function (*a*) in a modified form. When the earthworm's hæmoglobin has combined with carbon monoxide the animal consumes less oxygen, both at normal atmospheric and at lower oxygen pressures, although the greatest use of the hæmoglobin is made at oxygen pressures about half atmospheric.

As regards function (*c*), the amount of oxygen in the blood of Arenicola is sufficient to last the animal about an hour; it could therefore help to supply the animal's needs while buried in mud at low tide and then presumably unable to obtain fresh supplies of oxygen[2,3]. When in its mud tube under water, the ventilation movements of Arenicola are intermittent, and its hæmoglobin may act as a temporary oxygen store between successive ventilation periods[6]. In the gephyrean worm Urechis, the amount of oxygen combined with hæmoglobin is also sufficient to last the animal for about an hour, and is thought to act as a store both between ventilation periods and at low tide[7]. This assumed function of Arenicola and Urechis hæmoglobin lacks proof. Would these animals in their burrows use less oxygen if deprived of their respiratory pigment?

Chlorocruorin is a unique chemical relative of hæmoglobin, present only in the blood of a few kinds of marine worms[8]. Work in this laboratory recently concluded by Mrs. R. F. Ewer has shown that the chlorocruorin of Sabella exhibits function (*a*). Like earthworms, frogs and certain fishes[9], and unlike human beings, Sabella can be gassed with carbon monoxide and yet not be killed. In these circumstances chlorocruorin cannot combine with oxygen, and the gassed animals were found to consume less oxygen both at atmospheric and at lower pressures of oxygen in the environment. It is clear, then, that the function of chlorocruorin is to cover a certain proportion of the worm's oxygen consumption. That oxychlorocruorin would part with its oxygen to the animals' tissues, even when the worm is in well aerated water, could be foreseen from two circumstances: (1) the unloading tension of chlorocruorin is relatively high[8], and (2) we found that the oxygen consumption of Sabella declines soon after the oxygen pressure in the water decreases, so that the oxygen pressure in the tissues is presumably very low[10].

Carbon monoxide inhibits intracellular oxidase. Although the relative pressures of carbon monoxide and oxygen in our work on Sabella and Lumbricus made it very improbable that this had happened, it was made certain by further measurements of the oxygen uptake of tissue slices with and without carbon monoxide; they were not significantly different.

This work will be published in the *Proceedings of the Royal Society*.

Bilirubin in Urine

MANY chemical tests for bilirubin in urine have been described, none very satisfactory and none very sensitive. In blood, bilirubin is estimated quantitatively and qualitatively by the well-known method of van den Bergh, which will indicate accurately quantities diluted to one in a million; and Fouchet's reagent, which is sensitive, in the same circumstances, at the dilution of one in sixty thousand.

Hitherto, the van den Bergh test has not been applicable to urine without complicated preliminary manipulations. I have found a very simple manœuvre which enables the van den Bergh or Fouchet test to be applied to any specimen of urine with results that are reliable, sensitive and accurate. The method consists in the addition of ten per cent very finely powdered dried normal egg albumen to an aliquot portion of the urine under test; the mixture must be very well shaken until the powder has all been taken up. The van den Bergh and Fouchet tests can then be conducted with the albumized urine exactly as with blood serum, and with results comparable in sensitivity.

The method will be described in full later.

This new test has obvious application in cases of intravascular hæmolysis after blood transfusion, in cases of malaria, blackwater fever, Weil's disease, yellow fever, etc.

Mycorrhizal Habit in the Date Palm (*Phoenix dactylifera* Linn.)

THE date palm grows in Egypt in a great variety of soils and conditions. I have seen palms even growing on the seashore of the Gulf of Suez in places which are occasionally flooded with sea-water and where the *p*H of the soil ranges from 8 to 9. It was thought worth while to test the presence or absence of mycorrhiza in such a widely distributed plant.

In the preliminary tests carried out about two years ago, it was found rather difficult to get satisfactory material from old palms owing to the nature of root growth. However, I started to raise plants from seeds and examine their roots at intervals. It has been found that roots of seedlings up to eight months old and grown in the sandy garden of the Faculty of Science, Abbasieh, are free from mycorrhizal association. At such a stage marked swellings are recognized at the tips of some roots, and on their examination they have been found to contain no fungus. Nevertheless, in plants fifteen months old and grown in pots containing Nile silt, the mycorrhizal association is quite visible.

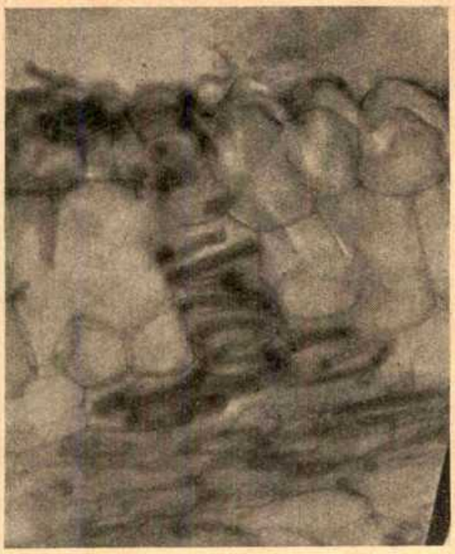

Fig. 1.
INVADING HYPHA WITH THE CHARACTERISTIC SPIRAL COILS.

Infected roots become hypertrophied, relatively more thickened and more opaque than the non-infected. They sometimes simulate coralloid roots.

The association is of the vesicular-arbuscular type. The extramatrical mycelium is easily observed and is of usual type. Root hairs are absent. The invading hypha forms a sort of appressorium before penetration. It is sometimes developed between the epidermal cells and it is also found directly opposite their outer walls. After invasion of the thick outer cellulose wall, the fungus proceeds through the cell cavity. It then develops in a very characteristic spiral fashion through a radial row of cortical cells 3–4 layers deep. After that it spreads laterally and inwardly for 3–4 layers producing these spirally coiled hyphæ within the cells. Then it ramifies in the cortex, producing intra- and inter-cellular mycelia and developing vesicles and arbuscules. Vesicles differ in shape and size and they may be inside the cells or between them. Arbuscules chiefly develop in the mid-cortex and in the deeply seated layers. In good material the whole of the cortical cells and the intercellular spaces, with the exception of the outermost 4–6 layers and the two layers next to the endodermis, are seen to be packed with the fungus.

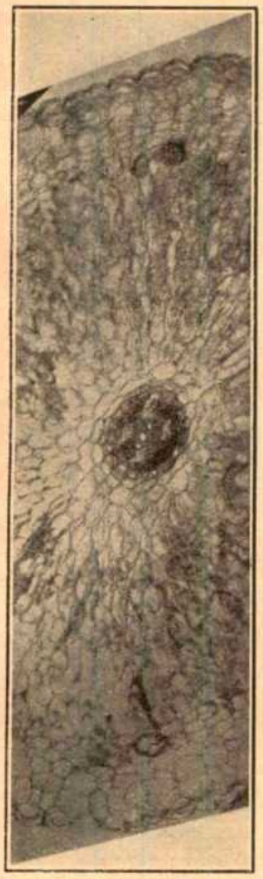

Fig. 2.

TRANSVERSE SECTION OF INFECTED ROOT SHOWING DISTRIBUTION OF THE FUNGUS. IN THE TOP PART SPIRALS AND VESICLES ARE SHOWN.

Cultivation of the fungus and its cytological characters are under investigation.

Blind Seed Disease of Ryegrass

It is now known that the blind seed disease of ryegrass, associated with low germination, has been present in Great Britain for at least four years. It appears that the true perennials are particularly susceptible and, as these are the more valuable forms, the disease is of considerable economic importance.

This disease of ryegrass was described in New Zealand by Hyde[1,2] and by Neill and Hyde[3]. The causal fungus was associated by these writers with the genus Pullularia, although it does not exhibit spore budding characteristic of that genus. When work was begun on this disease in Britain, a Pullularia form was isolated from seeds which were infected by the blind seed fungus[4] and, as at that time the paper by Neill and Hyde[3] was not available, the two fungi were not clearly distinguished. They are, under certain cultural conditions, very similar and therefore, in view of the original description of the blind seed disease as the 'Pullularia disease', it is desirable to record that, in Britain, the blind seed fungus as well as Pullularia sp. are often present on one and the same ryegrass seed. The exact identity, relative pathogenicity and frequency of occurrence of these fungi are under investigation.

Humpback Whales off West Australia

I notice in Nature of December 16, 1939, an interesting article by G. W. Rayner on the "Preliminary Results of the Marking of Whales by the Discovery Committee". In this article it is stated that a north and south migration of Humpback whales "along the western coast of Australia has been conjectured for some time past". While I am interested to note that Humpback whales marked in the Antarctic have appeared off the north-west Australian coast, I must criticize the use of the word *conjectured* in the above reference to western Australia.

During the years 1913–15 the movements of the whales on this coast were very carefully watched by the Norwegian whalers, and I had an opportunity on several occasions not only of observing this migration at different points, but also I had access to log books which indicated fairly clearly the times of appearance of the whales and the direction of migration.

The whaling season off the coast of north-west Australia is very definitely limited by the restriction in the time of occurrence of the breeding humpbacks. The dates of their arrival and departure are well known; and in my book "Whalemen Adventurers" (Angus and Robertson, Sydney, 1934) I have given a map to illustrate the direction of the west Australian migration so far as could be judged by the data available. I venture to think that this can scarcely be called a mere conjecture. The *place* whence the northern migrating whales *came* was a matter of conjecture, and here the results of the Discovery marking experiments have established new facts of value.

W. J. Dakin.

Department of Zoology,
University of Sydney.

Prof. Dakin's book "Whalemen Adventurers" and the map therein are well known to me. I am surprised that Prof. Dakin takes such exception to the passage in my article in which I express my view that "a north and south migration [of Humpback whales] along the western coast of Australia has been conjectured for some time past".

In this article the term 'migration' was used only when referring to Humpback whales, for it is only in that species that we have clear evidence, derived from whale-marking, of long-range movements at certain times of the year. Since this evidence is supplemented by the observed movements of Humpback whales off the north-west coast of Australia, we can now speak confidently of a migration along the west Australian coast. I feel that a distinction should be made between 'movements' and 'migrations', and do not consider that the local observations hitherto made fully established a 'migration' along this coast.

In his book, Prof. Dakin does not give very fully the evidence on which he bases his map and the few references to migration in his text. The log book records of which he speaks are for three seasons of very rapidly declining production and for the most part, I imagine, cover only a limited part of the north-west coast of the Australian continent in the vicinity of Norwegian Bay. Prof. Dakin is scarcely justified in extending his conclusions from this neighbourhood to the whole of the west coast, especially as he admits in his letter that the place whence the northward migrating whale came was not known. Whilst Prof. Dakin may have demonstrated the regular movements of Humpback whales off a part of the north-west coast, my remark referred to the west coast, which has a length of about 1,000 miles. For these reasons the word conjectured was used.

I admit our whale-marking data only show, *per se*, that Humpback whales once in the Antarctic may appear later off the north-west Australian coast, but this is a very positive fact and does support much that was previously, of necessity, conjectured.

George Rayner.

"Discovery" Investigations,

London, S.W.7.

Points from Foregoing Letters

R. S. Krishnan and T. E. Banks report the formation of ^{62}Cu by deuteron bombardment of copper, as a result of a new type of disintegration, namely, $(d - d, n)$ or $(d - p, 2n)$. The threshold for the production of this radio-element seems to be at about 7 Mev. and the yield increases rapidly between 8 and 9 Mev. Further evidence has been adduced to show that in the formation of ^{62}Cu the $(d - p, 2n)$ reaction is more probable than the $(d - d, n)$ reaction.

G. J. Kynch, E. H. Lloyd and W. G. Penney summarize the results of some new calculations on the energies, internuclear distances and vibration frequencies of the benzene and butadiene molecules. An argument is outlined leading to the conclusion that the heat of sublimation of carbon is 170 kcal./mol.

S. Melmore describes a kaleidoscope of eight mirrors ; it yields a solid tessellation of cuboctahedra and octahedra.

I. Berenblum, E. Chain and N. G. Heatley present evidence from the literature and from their own work to show that the respiration, glycolysis and respiratory quotient of tumour tissue does not differ fundamentally from that of the normal tissues from which the tumours are derived. In reply, F. Dickens and H. Weil-Malherbe consider that in view of the alteration of metabolism accompanying the formation of a hepatoma from normal liver, no general conclusion can as yet be drawn as to the occurrence of an alteration of metabolism in the development of cancer.

A chemical method for the estimation of vitamin B_6 in foodstuffs, using the diazo reaction or the phenol reagent, has been developed by M. Swaminathan.

F. Verzár and J. C. Somogyi show that although potassium is liberated from the muscles of normal cats by acetylcholine, and muscle contraction is stimulated, these phenomena do not occur with adrenalectomized cats. They suggest this is connected with the absence of glycogen re-synthesis after adrenalectomy.

Work by Mrs. R. F. Ewer on the function of the chlorocruorin of Sabella and by Dr. M. L. Johnson on that of the hæmoglobin of the earthworm (Lumbricus) shows that both pigments act as oxygen carriers at and below atmospheric oxygen pressures in the environment, and provide for part of the oxygen consumption of the worms.

Younis Sabet records some observations on the development of the mycorrhizal habit in the date palm. The infected roots become hypertrophied and more thickened. Before penetrating the cell wall, the invading hypha develops an appressorium ; once in the cell cavity it forms a characteristic spiral. Finally, the whole of the cortex (cells and intercellular spores) become packed with fungus.

The fungus which in New Zealand has been described as the cause of blind seed disease of rye grass resembles under certain conditions Pullularia sp. In view of the original description 'Pullularia disease', M. Wilson, M. Noble and E. G. Gray record that Pullularia sp. as well as the blind seed fungus are present. Investigation of these two fungi, as well as of others described on rye grass, is being carried out.

W. J. Dakin queries statements made by G. Rayner in his recent article on whale marking. Rayner states that he distinguishes between 'movement' and 'migration', the latter term only being used when discussing Humpback whales. Dakin's evidence is considered to show movement rather than migration, and his conclusions are thought to lack full confirmation. This has been supplied by the knowledge gained from marking experiments.

RESEARCH ITEMS

Prehistory in Haiti

EXCAVATIONS over a period of three months in 1935, carried out by F. G. Rainey and Irving Rouse, on eleven sites near Ft. Liberté Bay, Haiti, produced some twelve thousand specimens. A report on the excavations is about to be published, but in the meantime the specimens have been examined by the latter in the Peabody Museum with a view of testing the possibilities of a new technique of archæological analysis in elucidating the facts of both space and time relation in prehistory (*Yale Univ. Pub. in Anthropology*, No. 21; 1939). Of the eleven sites (all kitchen midden sites) five were small, consisting of a single deposit on a restricted area, and are termed "camp sites". The remaining six are groups of middens, deep and spread over a broad area, and are termed "village sites". Two phases are distinguished: the Flint Phase, without pottery and apparently food-gathering, and the Shell Phase, with pottery and agricultural. In the second, flint becomes rare and the place of the double-fitted axe is taken by the petalloid celt. From comparative analysis it is suggested that the people of Period I who were responsible for the camp sites migrated from the south-eastern parts of the United States by way of Cuba, being semi-nomadic and living in small groups. In Period II, the region may have been uninhabited. To Period III belong the Macady and Diale sites, settled by a people migrating from South America, possibly in Period II. Presumably, they spoke Arawak and brought agriculture and the petalloid celt, but not pottery. Probably it was the descendants of these people who inhabited the region in Period IV. They adopted the pottery of their Dominican neighbours in place of the local type which had been introduced from North America early in Period III.

The Delinquent as a Type

IN a paper read before the Second Institute of the Washington Child Adjustment Clinic (*J. Crim. Psychopath.*, **1**, 24; 1939) Dr. Ben Karpman, of Washington, D.C., who records four illustrative cases, maintains that there is no such thing as the delinquent as a type or personality, but that there are many persons who may be delinquent, in each of whom the delinquency expresses a different problem. The criminal offences for which they are sent to prison are different, the sentences are different and the crime of each means to each one individually something much more and different than it means to the others. Generally speaking, a delinquent is one whose behaviour is such that society must obviously take measures to defend itself against him, and delinquency refers mainly to petty transgressions as distinct from major crimes such as murder, highway robbery, etc. Transitional cases exist between the juvenile delinquent on one hand and the major criminal on the other who has passed the age of sixteen but has not yet quite entered manhood. Karpman's four cases of juvenile delinquency, whose ages ranged from eleven to fifteen, represent respectively the defective, the psychopathic, the neurotic and psychotic, each of which had a different background and a different crime motivation, though superficially they showed much resemblance to one another.

Substances which Modify Carcinogenic Action

DR. CRABTREE has investigated the effect of substances, which might be considered to inhibit metabolism of tissues, on the production of skin tumours in mice with the carcinogenic 3 : 4-benzpyrene. Certain reactive organic chlorine compounds which check glycolysis delayed the carcinogenic process but never completely inhibited it. The application of naphthoyl nitrile along with 3 : 4-benzpyrene to the skin of mice induced a high incidence of multiple warts. The carcinogenic agent alone usually produced single warts. A preliminary account of this work is given in the thirty-seventh annual report of the Imperial Cancer Research Fund.

Action of Methylcholanthrene on Normal Tissue Cultures

TISSUES from mice of a strain (C_3H), which are known to be particularly sensitive to the action of carcinogenic agents, have been grown in tissue culture in the presence of methylcholanthrene. W. R. Earle and Carl Voegtlin (U.S. Public Health Reports, **55**, 303; 1940) describe the changes which the cultures undergo in response to the carcinogenic agent. The initial effect of the carcinogen is to retard growth, and this is followed by gradual changes throughout each culture. The tissue finally had the appearance of cultures of malignant growths, but on injection into mice they did not produce tumours.

Japanese Anomura

GUSTAV MELIN describes a number of species of Pagurids and Galatheids from the Bonin Islands, Japan ("Paguriden and Galatheiden von Prof. Dr. Sixten Bocks Expedition nach den Bonin-Inseln 1914", *Kungl. Svenska Vitenskapsakademiens Handlingar*, Tredje Serien, 18, No. 2; 1939). There is also included a new species of the Thalassinid Callianidea (*C. planocula*). The descriptions are very carefully made and detailed, with good simple drawings of essential parts. The classification of the Pagurids is discussed at length and revised, and a clear key given for all the genera and sub-genera. Several new species of Eupagurus are described, and the new genus Paguritta established for *Paguritta gracilipes* n.sp. Among the Galatheids there are also new species including *Bathymunida quadratirostrata* from a depth of 70 fathoms, one of the specimens being a female with eggs. There are several species of Petrolisthes, one new, and a new species of Pachycheles. A note at the end of the paper by Prof. Balss states that this valuable addition to our knowledge of the Pagurids and their relatives was completed in 1918–21, but comparison with other work from Japan shows that the new species included have not been described by more recent workers.

Microbiology of the 'Leaf Carpet'

UNDER this term, D. J. Scourfield discusses the microscopic life in the continuous carpet of decaying leaves that forms the characteristic feature of the upper layer, the "mor", of the forest soil. The paper appears in the *Essex Naturalist* (**26**; 1940) and is extremely appropriate to the activities of a natural history society. Mr. Scourfield makes it clear that our information about the characteristic fauna and flora of this leaf carpet is exceedingly scanty, and that a very profitable field lies ready to the investigation of the field naturalist. Knowledge of the organisms characteristic of this position must precede any substantial advance as to the influence this leaf carpet has upon the forest, though it is abundantly clear that the leaf carpet follows quickly upon the closure of the forest canopy and initiates the sequence of changes in the habitat that characterize the establishment of the forest. No fewer than sixteen groups of organisms, present in the leaf carpet, are passed briefly in review. Some of these groups are still little worked out and require, as Mr. Scourfield emphasizes, the collaboration of a number of specialists, but here is a field entirely appropriate to the naturalist and ultimately, probably, of great interest to the forester.

Crossing Experiments with Rusts

THE recent discoveries of the function of the rust spermatia or pycnospores have permitted an active investigation of strains by crossing methods, and Thorvaldur Johnson and Margaret Newton, of the Dominion Laboratory of Plant Pathology, have just reported upon an extensive crossing and selfing experiment with physiological races of oat stem rust (*Canadian J. Res.*, **18**, 54–67, 1940). In crosses the less virulent characteristics are usually dominant, and heterozygous lines, when selfed, tend to produce more virulent strains. Reciprocal crosses suggest that the cytoplasm, as well as the nucleus, contributes to the inheritance of certain pathogenic characters. One great difficulty, of course, is the scarcity of characters the inheritance of which can be studied. In crosses between races of normal (red) and orange uredospore patches the red colour has invariably proved dominant. Selfing studies of one race carried out with teleutospore material of different age give evidence of a marked genetical change in the material brought about in four years, presumably through the ageing of the teleutospores. Normally all infections of this strain produced pycnidia, but in the old material half the infections showed no indications even of rudimentary pycnidia.

Control of Tobacco Mildew

THE downy mildew fungus disease of tobacco is of sporadic occurrence in certain of the United States; but two simple and effective methods of control have been described by P. J. Anderson (Conn. Agr. Exp. Sta. Circular 128, New Haven, Conn.; January 1939). Both methods involve fumigation of the seed bed, and the fumigants recommended are benzol or paradichlorobenzene. Sidewalls and sashes, which normally cover the beds, are made as air-tight as possible. Benzol is evaporated from shallow pans or from wicks placed in suitable vessels; paradichlorobenzene crystals are placed in wire baskets at suitable intervals along the beds. Both methods are curative and not preventive measures, and both offer a useful measure of practical control.

apparatus, consisting of a film balance divided into two compartments by a water-tight flexible float, has been used with solutions of hydrocinnamic acid, potassium laurate, sodium butylbenzene sulphonate and lauryl sulphonic acid. The surface tension of hydrocinnamic acid solutions is not fully established until after periods of time enormously greater than those expected from classical diffusion processes. A type of curve with a minimum is established, and in this a trace of solute first lowers the surface tension of the solvent while further small addition raises the surface tension to a low maximum or constant value (lauryl sulphonic acid; sodium butylbenzene sulphonate). With potassium laurate, addition of alkali appears to lower the flat maximum to the value of the minimum.

Nitrogen Tribromide

Nitrogen chloride and iodide have been known for many years, but the bromide has not yet been isolated. Bromine appeared to be as passive towards nitrogen as towards oxygen, oxides of bromine having been discovered only within recent years. The existence of NH_2Br and $NHBr_2$ in solution seems fairly certain, and the azide N_3Br has been prepared, but the compound NBr_3 has not yet been obtained. Recent investigations, however, of the mechanism of the reaction between ammonia and bromine at low temperatures (Schmeisser, *Naturwiss.*, 28, 63; 1940) show the existence of an ammoniate of nitrogen tribromide with the formula $NBr_3.6NH_3$. The compound was obtained when bromine and excess ammonia were mixed at 1–2 mm. pressure, and cooled to $-95°$. It is a dark purplish-red compound, which decomposes violently above $-70°$ into nitrogen, ammonia, and ammonium bromide, according to the equation $NBr_3.6NH_3 = N_2 + 3NH_4Br + 2NH_3$.

An Acoustic Generator

Prof. Hartmann of the Physics Laboratory of the Technical College, Copenhagen, discovered more than twenty years ago that if a small resonance tube is placed with its mouth facing a nozzle from which air at a pressure of a few atmospheres is issuing, at certain distances from the nozzle the resonator becomes the source of a note of high pitch and considerable intensity. With the aid of funds from the Carlsberg, Oersted and Mansted Foundations the mode of action and the best form of the apparatus have since been investigated by Prof. Hartmann and his assistants, and the results are collected in a well-illustrated paper of more than 200 pages by himself, Peter and Elisabeth Mathes and Freimut Lazarus (*Ingeniorvidenskabelige Skrifter* of the Academy of Technical Sciences, No 4; 1939). In general, the jet of air issues from a nozzle of 2–6 mm. diameter, the excess pressure being 1·8–4·8 atmospheres, and the resonator has its diameter and length equal to the diameter of the nozzle. The wave-length of the note emitted varies from 1 to 5 cm., according to the position of the resonator and the air pressure used. The intensity of the sound is measured by the Rayleigh disk, the pressure disk, and three other methods. It is greatest in a direction nearly at right angles to the axis of the apparatus, and the acoustic efficiency is a maximum of about 5·5 per cent when the excess pressure is 1·5 atmospheres.

Sensitometry of Photographic Material used in Astronomy

D. R. Barber, Norman Lockyer Observatory, Sidmouth, has published a paper on this subject (*Mon. Not. Roy. Astro. Soc.*, 100, 3; January 1940) in which he gives a full description of his investigation on the influence of three different developers upon various negative materials, comprising three blue-sensitive, three 'orthochromatic', and three panchromatic emulsions. A variety of diverse characteristics is essential for the ideal developer, from the astrophysical point of view, among which may be noted high contrast, combined with a low value of background (chemical) fog, and freedom from excessive graininess in the case of super-speed materials. In actual practice, however, a compromise is essential, since a pronounced reduction of graininess resulting from the use of ultra-fine emulsions, or specially compounded developers, will be obtained only at the expense of a lowered effective threshold response. Each plate was calibrated by the tube sensitometer (*Bull. Norman Lockyer Observ.*, 1, 14; 1938), and blue light through a Wratten No. 47*a* cemented filter, having a transmission band from 3750 A. to 5200 A., was used in the calibration, as the effective response of a photographic material is known to depend on the quality of the radiation incident upon it. A number of diagrams shows the change in the effective response of the emulsion at different densities, and this is expressed as a magnitude gain or loss, referred to standard development. The main conclusion reached is that the standard metol-hydroquinone developer, even when used with a wide variety of sensitive materials, always produces results most suitable for use in astronomical photography.

Alpha Photometric Observations of the Solar Spectrum

David S. Evans has published a paper criticizing some of Unsöld's views, in particular that which suggests that the Balmer series of the solar spectrum is formed effectively by pure absorption (*Mon. Not. Roy. Astro. Soc.*, 100, 3; January 1940). Evans undertook a programme of observations of the centre-to-limb variations in the contour of $H\alpha$ and carried out the work with the Oxford solar telescope. The spectroscope used was of the Littrow form with two 60° prisms and one 30°. Its aperture ratio was the same as the telescope, its dispersion being 2·06 A. at $H\alpha$ and 1·47 A. per mm. at the sodium D lines. At the suggestion of Prof. H. H. Plaskett, the D lines of sodium in absorption were used for the determination of the instrumental pattern of the spectroscope and of the amount of scattered light; a preliminary account of the method appeared in the *Observatory* (62, 231; 1939). A new method of drawing characteristic curves was used, and if this introduced errors into the results, these would have revealed themselves as a correlation between determined residual intensity and plate opacity. No such correlation, however, was found for plates ranging in opacity from 0·40 to 0·97. A comparison is made with the results obtained by other workers, Minnaert, Thackeray, Royds and Narayan. The low value of the equivalent width found by the last two workers is suspected to be due to their lack of precautions to guard against scattered light. On approaching the limb, it has been found that the residual intensity increases at each wave-length. There is some support for the view that uncompensated cycles are not of importance in the formation of $H\alpha$.

THE EGG AS FOOD

ONE of the most difficult of the tasks which has always confronted the scientific worker possessed of a proper appreciation of his responsibilities to society has been the choice of a way of making his results known so that they will do most good. Material of an abstruse or technical nature is fitly presented to a learned society. Such a society, however, only comprises producers of knowledge. It is much more difficult to pass on knowledge to the consumers: those who make use of it. Nutrition is a branch of science which applies so directly to the population at large that any attempt to shorten the distance between the scientific investigator and the dining-table is to be viewed with especial interest.

The Nutrition Panel of the Society of Chemical Industry, the membership of which is made up of workers in all branches of science ranging from the academic Scylla of biological oxidations and reductions to the practical Charybdis of canning, has conceived itself to be peculiarly well fitted for the task of disseminating the knowledge of nutrition. A series of meetings has been planned at each of which a single food will be discussed. These meetings are not addressed to a purely scientific audience, neither are they intended to be 'popular'. Rather are they for all those whose business it is to take an intelligent interest in nutrition.

The first meeting of the series was held on April 24 and was concerned with the egg as food. Besides the members of the Society of Chemical Industry itself, representatives of educational, agricultural, and medical associations were invited, as well as members of the great women's associations interested in general welfare.

Dr. Joseph Needham, of the Biochemical Laboratory, University of Cambridge, who spoke on "The Biological Nature of the Egg", pointed out how complex is the structure of the eggs of birds and other vertebrates. In fact the embryo, which is eventually to develop into the new animal, only occupies a very small space within the whole egg. The remainder serves, in one way or another, to keep the organism alive until it is hatched. It is interesting to note that this is not the case among lower animals. The young octopus in its egg is not supplied by its mother with enough copper with which to make its blood pigment, but must obtain more for itself from the surrounding sea. Newts and frogs in their eggs also depend on the environment for water. Birds' eggs, however, represent a type of perfectly 'closed-box' structure which requires many ingenious devices in order to survive. One of these, by which the bird saves itself from being poisoned by its own by-products, is the fact that the developing embryo does not excrete nitrogen as ammonia or urea but in the form of uric acid, which is more easily deposited as crystals.

Dr. Ethel M. Cruickshank, of the Department of Agriculture, University of Cambridge, who spoke on the "Chemical Composition of the Egg", pointed out that the hen can be regarded as a physiological machine for turning raw materials into human foodstuffs. The amount of such human food that the hen can produce in a day depends on a number of factors, but to a large extent it is true to say that the bigger the hen the larger the egg. The number of eggs a hen lays in a year is a different matter; an interesting point is the fact that high production has little or no detrimental effect on the quality of the eggs. In considering the composition of the egg one must divide it into three parts. The shell is principally made up of calcium carbonate, although small amounts of magnesium, phosphorus and organic matter are present. The 'white' is composed of at least four different proteins and can be divided into layers of thick and thin white. The proportion of thick to thin white influences the culinary value of the egg. Together, the proteins in the white contain all the essential amino acids for 'first-class' protein. Egg white contains minerals and also supplies valuable amounts of vitamin B_2. The yolk contains two proteins which are also found to be of 'first-class' quality. Besides protein the yolk contains 30–32 per cent fat. Numerous minerals are present, including relatively large amounts of easily assimilable iron. Vitamins A, D, B_1 and riboflavin are also present. The anti-rachitic vitamin D is of great significance in the diet. Dr. Cruickshank also discussed the factors in the diet of the hen which might give the yolk an unpleasant taste or a strange colour. Although the amount of fat, and hence the total food value of the egg, can only be influenced to a slight extent by the diet of the hen, the nature and flavour of the egg can be very strikingly altered by feeding mashes containing, for example, hemp seed or linseed oil. As to vitamins, it is essential that they should be abundantly present in the diet of the hen in order that her eggs may be of high nutritive value: and it is well known that a thin shell is obtained by feeding a hen a diet poor in calcium. However, the calcium contents of the yolk and the white are not affected. The amount of iodine in eggs is affected by the amount in the hens' food, although iron and copper appear to be independent of the amount present in the diet.

Dr. S. K. Kon, of the National Institute for Research in Dairying, Reading, spoke on the nutritive importance of eggs in the diet. He stressed that eggs share with milk the ability to cover nutritive requirements during the period of rapid development. The shortage of vitamin D and iron in milk is admirably supplemented by eggs; the deficiency of eggs in calcium is made good by their association with milk. The vitamins, minerals and 'first-class' protein in eggs make them one of the protective foods. In particular, eggs supplement very well the proteins present in cereals. Dr. Kon showed in detail how eggs contribute to the various factors of a good diet.

Dr. R. B. Haines, of the Low Temperature Research Station, Cambridge, spoke on the preservation of eggs. He pointed out that hens' eggs are in a state of rapid change. The aim of storage is to retard or stop this change and prevent the attack of outside agencies such as micro-organisms. Although storage only affects the nutritive value of eggs to a very minor degree, any loss of palatability and cooking quality is a clear indication that certain slight chemical changes have taken place. Dr. Haines mentioned three methods for the large-scale storage of eggs—cold storage, storage with the partial addition of carbon dioxide, and full gas storage. For other purposes, drying or freezing can be used. Problems connected with the storage of eggs lead to the consideration of questions of production and handling. For example, 'thick white' is apparently due to the individual hen. Again, spoilage of eggs by the invasion of bacteria is influenced by the structure of the egg-shell, which may vary greatly in successive eggs from the same hen or by the 'washing' treatment which the eggs receive. Among many other topics upon which Dr. Haines touched were 'swollen' and 'flabby' yolks due to loss of moisture, 'watery whites', 'sunken' and 'sided' yolks due to chemical changes and eggs with 'whiskers' due to the growth of fungus on the shell.

Miss Mary Andross, of the West of Scotland College of Domestic Science, Glasgow, gave the final paper on the subject of "The Cooking of Eggs". Research in domestic science concerns itself with the effects such factors as temperature, time, rate of cooking, acidity, or the addition of salts may have on the nutritive properties of eggs which are boiled, poached, fried, scrambled or made into omelets, custards, mayonnaise, meringues, angel cakes, or sponge cakes. Another important factor which is the subject of scientific investigation is the effect of the age of the egg in relation to its cooking qualities. Miss Andross presented the results of a large amount of her own original work on these points. She also discussed the waste of food value which may take place in different methods of cooking. In making a scrambled egg, for example, 13·5 per cent of the original food value is left behind in the various bowls and dishes used in cooking it. Miss Andross concluded by discussing the effects which different treatments may have on the digestibility of the food.

In the course of a general discussion a number of further points were considered. These included the 'too fresh' egg; the problem of sensitivity to egg white; coagulation of egg proteins during cooking; reconstitution of dried eggs; and many others.

If the following meetings of the series on other foods are as complete as the first, the collected papers will form a text-book of unrivalled excellence. It would only then remain to see whether the farmers, administrators, cooks and diners of England are availing themselves of the information thus collected to determine whether the plans of the Nutrition Panel have succeeded.

FUNDAMENTALS OF CLASSICAL ELECTRIC AND MAGNETIC THEORY

By Dr. G. Burniston Brown
University College, London

Ever since the Committee of the International Electrical Congress in 1932 was forced to resort to a majority vote in order to decide upon the introduction of the Oersted, the general uneasiness of physicists with regard to the difference between induction and force has been augmented rather than allayed; and all the more so when the secretary of the committee, Prof. Henri Abraham, maintained that there were at least six definitions of the permeability (μ), and that it is not possible either to show that they are the same or different[1].

A meeting of the Physical Society on May 3 was devoted to this problem and to a discussion of the presentation of the classical theory of electricity and magnetism in general. The discussion was opened by the present writer, who claimed to show that the first three definitions of μ, which are fundamental to electromagnetic theory, are equivalent. Abraham's last three definitions are concerned with magneto-optics and are not of the same importance.

In order to demonstrate this equivalence the author made use of a point of view which is gaining ground among writers on the philosophy of science, namely, that the ultimate meaning of any concept to which numbers are attached involves the consideration of an act of measurement either in an actual experiment or in a "theoretical-experiment". This may be looked upon as a special form of the general thesis put forward by Ogden and Richards in their book "The Meaning of Meaning"[2], that all meaning involves what they termed a "sign-situation". In the special form given above, it is the basis of Sir Arthur Eddington's philosophy of science, and he has called a sign-situation a "gesticulation"[3].

If this principle is applied to the concepts of "force on a pole" and "force on a current element", it can be shown that the former requires a rod-shaped cavity and the latter a disk-shaped cavity for the act of measurement, and thus the cavities of the classical treatment of Maxwell and Kelvin arise naturally instead of arbitrarily. Application of the same method to the theoretical-experiment in which the principle of the conservation of energy is used to show that the induced electromotive force is equal to the rate of change of magnetic flux, shows clearly that it is the rate of change of the normal induction which is involved and not the force. This is not often shown clearly in the text-books.

Use can be made of Poisson's fictitious-layer theory to find the force in the cavities. Poisson's treatment rests solely on the inverse square law, and the assumption that the field of a polarized substance can be treated as consisting of the fields of a large number of doublets. If we take the number of doublets per cubic centimetre to be n and their polarizability α, then we readily find the relation with K, the dielectric constant, to be

$$K = 1 + 4\pi n\alpha.$$

This formula is derived directly from classical macroscopic theory and has the great advantage that it is independent of theories of molecular structure. It assumes that the polarization is proportional to the internal field but is independent of whether the polarization is due to separation of charges or rotation of doublets already present. It seems that Mossotti took the polarization to be proportional to the external field, and this causes his formula to differ from that given above. The formula of Clausius, since made great use of by Lorentz and Debye, would, however, seem to involve an unjustifiable mixture of macroscopic and microscopic considerations. One way of putting it briefly is this: a piece of dielectric is placed in the field of a condenser and Poisson's fictitious-layers of charge are placed on its boundary; then a spherical portion (which is also large compared with molecular structure) is removed, but in this case Poisson's surface charge is omitted and it is considered from a purely microscopic point of view. The result is that there is difference between the formula of Clausius and that of Mossotti. This has been overcome by adopting the former, using a hyphen, and calling it the Clausius-Mossotti formula!

Another application of the epistemological principle already mentioned, namely, that a physical concept receives its precise meaning in an experiment or theoretical-experiment, is of great use in clearing the obscurity that surrounds the theory of dimensions. The dielectric constant K and the permeability μ do not, in some mystical way, tell us anything about the 'nature' of electricity and magnetism, or the difference between them. K and μ are symbols and mean just as much as their definition implies and nothing more. K is defined as the ratio of numbers obtained by the same conventional set of operations performed first on the material in question, and secondly on free space. It is easy to show that μ is exactly analogous to K. Consequently, both K and μ are dimensionless. In the determination of the ratio of the electrostatic to the electromagnetic system, it is usually forgotten that the conventional set of operations is different: in the case of the capacity of a condenser, for example, only a scale is required on the E.S. system, whereas on the E.M. system a clock is required in addition. The symbols representing the operation (the dimensions L and T) do not therefore cancel and the ratio is c^2 cm.^{2}/sec.^{2}. In the expression for the velocity of electromagnetic waves, $\frac{c}{\sqrt{K\mu}}$, it is c which has dimensions.

In the discussion which followed, there seemed to be general agreement that the formulæ of Mossotti and Clausius are not free from errors in their derivation. Strong resistance was, however, shown to the attempt to deprive K and μ of their dimensions, and declarations of faith that B and H were 'really' different were made, including that of a former member of the International Committee. Other difficulties, such as that of providing a satisfactory proof of the expression for the energy involved in a hysteresis-cycle, were also discussed.

GEOLOGY IN GREAT BRITAIN

Reports for 1936 and 1937

PART I of the "Summary of Progress of the Geological Survey of Great Britain" for 1936[1] contains an appreciation of the work of the late Dr. Bernard Smith, who had held the office of director for less than a year at the time of his death in 1936. Pending the appointment of a new director, Dr. W. E. P. McClintock served as acting director and was in general charge of the Survey and Museum until the new director, Dr. E. B. Bailey, took up duty. The report gives the usual particulars of the routine work carried out during the year under review. Forty maps and ten memoirs were issued, some of which have already been reviewed (see NATURE, 141, 696; 1938).

Part II[2] contains a series of papers on subjects of special interest. The stratigraphy of the Upper Coal Measures of South Lancashire is described by R. C. B. Jones and compared with that of North Staffordshire and North Wales. W. B. Wright contributed an account of the Anthrocomyas of the Lancashire Coal Measures in a paper which claims to be the first serious attempt to show that the detailed Lancashire system of sub-zones has a stratigraphical significance elsewhere, notably in Scotland, where eight of the sub-zones have been detected in their appropriate sequence. C. J. Stubblefield places on record information concerning the availability of specimens of fossils figured in the 1848 memoir on the Malvern Hills and other Palæozoic districts. Borings are described by R. L. Sherlock (through a Keuper succession in Shropshire) and M. Macgregor (through Carboniferous strata in Lanarkshire). An investigation of underground water pressure in the Spilsby Sandstone of Lincolnshire is recorded by H. H. Swinnerton. Structural features in the metamorphic rocks of parts of Shetland, notably the striations known as 'lineation', are described by T. Robertson. Improvements in the Lawrence Smith method of alkali determination are suggested by C. O. Harvey.

In the "Summary of Progress" for 1937[3] (no longer called Part I), the new director gives an interesting history of the changes in scope which the "Summary of Progress" has gradually undergone since its introduction in 1898 (for 1897) by Sir Archibald Geikie. Since 1927 the "Summaries" have been divided into two, or sometimes three, parts, the second and third parts being devoted to contributions on special topics, such as those referred to in the preceding paragraph. It has now been decided to issue papers or monographs of this kind in an independent publication to be called the *Bulletin of the Geological Survey of Great Britain*. The first two *Bulletins* have already appeared and are noticed below. It is also announced that it is intended to issue regional accounts of the ore deposits of particular districts. Devon–Cornwall and the South Pennines were selected for examination during 1938. Twenty-two maps and eight memoirs were published during 1937, and at the close of the year there were forty-four maps and six memoirs in the press. The "Summaries" for 1938 and 1939 are not yet available.

Bulletins

Bulletin 1[4] contains nine papers, of which six are concerned with the Carboniferous System. The discovery of a marine band with goniatites is announced by L. H. Tonks from the Middle Coal Measures of Co. Durham. R. Crookall reviews all the available evidence regarding Kidston's claim that an almost complete change in the recorded plant life of the Carboniferous occurs at a particular level in the Millstone Grit of Britain. The conclusion is reached that only two plants have been satisfactorily proved to trespass from one side to the other of this so-called plant 'break'. An interesting account is given by M. Macgregor of old coal-workings encountered during excavation for hospital foundations at Cowglen, near Glasgow. Much new information is furnished regarding the freshwater mussels of the Coal Measures: in Yorkshire, by W. B. Wright; and in Lancashire, by W. Dewar.

A description of unusual palæontological interest is given by F. W. Anderson of a Lower Carboniferous species of a rare group of echinoderms; although this particular species had not been previously recorded, thirty-three specimens are crowded upon a single small slab collected from the core of a boring in the Scremerston Series in Northumberland. Those interested in the Jurassic will find an important paper by L. F. Spath on the ammonites of the Warboys pit in the Oxford Clay of Huntingdonshire. C. O. Harvey contributes a description of a simple method for determining water in silicate analyses. The history and use of the petrographic term 'plagiophyre' are outlined by A. G. MacGregor, who proposes that in future it should be used only as a group-name. The *Bulletin* is effectively illustrated and has an adequate index.

Bulletin 2[5] maintains the high standard of the first number and contains eight papers on subjects covering a much wider range of interest. A. F. Hallimond and J. T. Whetton demonstrate that a magnetometer survey can be usefully undertaken in search of hæmatite ore-bodies under considerable depths of cover. An account is given of a magnetic survey in South Cumberland and Furness. The difficulties of the method are critically considered. In another paper A. F. Hallimond describes magnetic observations on the Brockhill dolerite dyke of Worcestershire. Certain oil seepages in Lancashire, of which the most important occurs in peat near Formby, have been investigated by F. W. Cope; a biological report is added by Kathleen B. Blackburn. Both authors conclude that the oil is of underground origin and is not a derivative, as formerly supposed, from modern plants in the peat. J. E. Richey and W. Q. Kennedy describe in detail their recent researches on the Morar anticline with its Sub-Moine core and its envelope of Moines. The two series appear to be separated by a great unconformity.

E. B. Bailey reviews the Caledonian structural elements of Skye; he confirms, with some modifications, Clough's reading of a tectonic window near Ord. New reasons are given for regarding the Tarskavaig 'Moines' as Torridonian. Rocks of the Moine Series are also described by T. Robertson, these being in and near the Garry-Ericht water-tunnel of the Grampians. Special attention is given to structural features, including lineation. In south-west Cornwall the Meneage Crush-Zone has long withstood satisfactory stratigraphical analysis. C. J. Stubblefield now records the presence of Lower Devonian strata at two localities and throws considerable doubt on former identifications of alleged Ordovician and Silurian fossils. R. Crookall describes plant remains in a red sandstone regarded as probably of Lower Carboniferous age.

MEMOIRS

The volume on Area I of the "Economic Geology of the Central Coalfield" of Scotland[6] completes a series of nine memoirs on this important region. It describes in detail the mineral resources of the Kilsyth–Kirkintilloch district, an area of 66 square miles mainly in Stirlingshire and Dumbartonshire. Along the north are the steep slopes of the Kilsyth Hills and Campsie Fells. The through valley that has formed a natural line of communication between the Forth and Clyde throughout the centuries stretches across the area. The south-eastern part is undulating drift-covered moorland, relieved by hills and crags where dolerite sills come to the surface. Apart from superficial deposits, which provide good building sand and gravel, and a small inlier of Old Red Sandstone, the rocks described are of Carboniferous age. The Limestone Coal Group, around which centres the chief economic activity of the district, has long yielded coal and ironstone. In recent years anthracite has been successfully exploited. Such products as limestone, building stone, moulding sand and fireclay are provided by other strata, and large quantities of road metal are obtained from the well-known quartz-dolerites of Kilsyth. Special chapters are devoted to the structure of the area and to more systematic descriptions of the various economic products.

The memoir describing the geology of the "Shrewsbury District"[7] deals with some of the most geologically attractive parts of Shropshire, including the Longmynd, Caer Caradoc and the Wrekin, where Pre-Cambrian rocks appear boldly at the surface; and Wenlock Edge, made famous by Murchison in his pioneer work on the Silurian System. The district is remarkable for the great variety of its rocks and fossils and for the immense range of time which they represent. As a result many geologists have here received their first training in field work, and some of them have returned to repay their debt by detailed research. The Survey geologists have done full justice to a classic area of unrivalled interest. Successive chapters deal with the Pre-Cambrian, Cambrian, Ordovician and Silurian rocks; the Carboniferous formations of the Coalbrookdale coalfield and the minor fields near Shrewsbury; the Bunter sandstones and pebble beds; and the superficial deposits, mainly glacial, which lie across the outcrops of all these 'solid' formations. Mineral products and water supply form the subjects of the final chapter. A series of appendixes includes two of special interest: "Fossil and Fossil Locality Lists" and "Age-Determinations by the Helium Method". The latter records the ages of the Clee Hills and Little Wenlock basalts as 240 and 260 million years, respectively, and so confirms the Carboniferous age now assigned to them.

The "Wigan District"[8] is mainly occupied by the productive Coal Measures of the western half of the South Lancashire Coalfield. In the west and south-east these lie below a covering of Triassic sandstones, while to the north-east the Lower Coal Measures and Millstone Grit rise to form a high moorland that merges into the Pennine uplands. Over the lower ground lies a widespread mantle of glacial deposits which in turn are partly hidden in the west by wind-blown sands and peat-mosses. The memoir records important additions to our knowledge of the Coal Measures. Zonal correlation by freshwater faunas has been extended well into the area from the adjoining Manchester sheet. Many new features of tectonic interest have become apparent and are recorded in a valuable chapter on structure and faulting. The Upper Coal Measures are found to be unconformable on the Middle Coal Measures, certain folds in the latter having been formed prior to the deposition of the former. Fossiliferous Permian marls discovered in the south of the area are of economic importance in regard to the exploration of the coalfield concealed beneath them. Special chapters deal with this topic, and with the palæontology of the Coal Measures, the economic products, and the glacial geology.

REPORTS ON MINERAL RESOURCES

The report on gypsum, anhydrite, celestine and strontianite[9] is now in its third edition. Since the second edition appeared in 1917, anhydrite, which was then a waste product, has become a valuable raw material in the manufacture of ammonium sulphate and sulphuric acid. The gypsum industry has greatly expanded as a result of the development of gypsum plasters and cement. Celestine and strontianite are the only sources of strontium compounds. These are used in the beet-sugar industry, as fillers in special paints and gramophone records, and for red flares in pyrotechny. The report gives details of the geology, mode of occurrence and distribution, mining and quarrying, uses and treatment, and reserves and statistics of these four minerals.

The report on the "Granites of Scotland"[10] brings together in compact form accounts of the distribution, mode of occurrence and leading characteristics of the principal Scottish granites, intended primarily for the use of those engaged in the granite industry. The first three chapters deal in succession with the development of the industry, with the mineralogical, chemical and physical properties of granite, and with the distribution and age-relationships of the occurrences. Later chapters provide details of the granites of north-east Scotland, of the Galloway district in the south-west, and of the Western Highlands. These include all the most important centres. Special attention is given to granites at present being wrought, and an account is given of the methods of working in active use. Other occurrences of granite throughout Scotland are also briefly described. A list of the quarries in operation during 1938 is appended.

RADIO FREQUENCY WAVE GUIDES

WITH the continuous extension of radio research to increasingly higher frequencies, it is not surprising to find occasionally that radical changes in technique and equipment occur. Such changes are already envisaged in the practical application of decimetre and centimetre electric waves, that is, the wave-length band from 1 cm. to 100 cm. So long ago as 1897, Lord Rayleigh gave a mathematical analysis of the propagation of electric waves along hollow tubes of either circular or rectangular cross-section, and showed that this type of transmission could take place only when the wave-length was of the same order as, or less than, the cross-sectional dimensions of the tube. Consequently this subject attracted little attention until about 1935, when suitable methods of generating these very high frequencies had been developed. Since this date the matter has been investigated in some detail in the United States, notably in the Bell Telephone Laboratories and the Massachusetts Institute of Technology, and also to a lesser extent in France and Germany.

A good review of the investigations conducted in the past few years was given by Dr. J. E. Houldin in a paper read on February 19 before the London Students' Section of the Institution of Electrical Engineers. It has been shown by analysis and verified experimentally that several types of waves can exist within the tube, but particular attention has been devoted to four of these. As is to be expected, there is a critical free-space wave-length above which no transmission along the tube takes place. Tubes having diameters of the order of 10 cm. appear to be practically convenient for use in the wave-length band 10–30 cm. By filling a copper or bakelite tube with water, the effective wave-length in the tube is reduced, with certain practical advantages for experimental work.

The velocity of propagation and attenuation of the waves depend upon the type of wave used, the wave-length and cross-sectional dimensions of the tube and the nature of the dielectric with which the tube is filled. It has been shown that at wave-lengths of 10 cm. and below, the hollow metal tube has an attenuation per unit length smaller than that of a co-axial cable of zero dielectric loss and the same external diameter. Owing to the omission of the central conductor and its dielectric supports, the hollow metal tube is simpler and cheaper to construct.

If an open-ended metal tube be excited with oscillations of suitable wave-length, the waves travel towards the open end and are radiated into space. Such radiation may be either vertically or horizontally polarized, or a combination of these, depending upon the type of waves set up in the tube. This radiation is transmitted predominantly forward, and by the use of a suitable flared horn on the open end of the tube, a well-defined beam is obtainable.

Experiments with various horns and tubes have shown that the gain of energy transmitted in the desired direction over that given by an omni-directional radiation is comparable with that obtained in the practical use of antenna arrays on the wave-lengths of 10–100 metres used in the beam system of short-wave communication.

SEVENTY YEARS AGO

Nature, vol. 2, May 19, 1870

Scientific Education

The leading article, under this title, discusses the facilities for training in the sciences available in Great Britain, with special reference to the Royal Commission recently appointed to consider Government aid to science. Referring to the Science and Art Department, it has been questioned whether this scheme has fulfilled the purpose for which it was originated. While the advantages of the scheme have been great, in that it is under the direction of men of the highest eminence, it is contended that the scheme operates mainly for the benefit of the technical schools founded by Government, and thereby forces an official plan of education upon the country. "To such we would remark, that the quantity of Science taught is so small, that it is not wise to attempt in any way to reduce that quantity; but it is certainly to be wished that the Commission should carefully inquire whether this method is one calculated to extend a sound Science education over the whole country".

A plea is made for consideration of the claims of such independent institutions as University College, London, King's College, London, and Owens College, Manchester.

Intellect and Size of Brain

According to the *British Medical Journal*, the weight of the late Sir James Simpson's brain, including the cerebellum, was 54 ounces. While, as is well known, the ratio between intellect and size of brain is by no means close, yet there can be no doubt that it is very important. Most of our great men have had large crania. The male brain ranges between 46 and 53 ounces, its average being 49½ (Quain and Sharpy). That of Cuvier is stated to have weighed 64 ounces, and that of the late Dr. Abercrombie 63 ounces, but it is possible that some error may have crept in through the use of weights of different standards. If not, Sir James's brain, whilst much above the average, did not nearly reach those of the celebrated men we have mentioned; but at the same time, the convolutions were remarkably numerous; they were, says a correspondent, "twisting and turning round on each other as if they could not find room within the head. The island of Reil was very wonderful".

An interesting application of photography to legal evidence has just taken place. The Spanish Government having refused to give up the *Tornado*, an English vessel captured some time since, or to give compensation to the owners, our own Government has acquiesced in the decision, a photographic copy of the private instructions given to the captain by the owners having proved conclusively the more than doubtful character of the vessel.

Correspondence on the "Strange Noises heard at Sea off Grey Town" continues. Charles Kingsley relates his own experiences and suggests that Drum fish (Pogomias) are responsible; Staff Capt. F. J. Evans, F.R.S., also quotes his own experiences and suggests "musical fish or shells"; H. P. Mallet suggests the presence of gas-bubbles rising from a mud containing much vegetable matter.

FORTHCOMING EVENTS

[*Meetings marked with an asterisk are open to the public.*]

Monday, May 20

Royal Geographical Society, at 5 p.m.—Prof. O. T. Jones, F.R.S.: "Oceanic Shelves".

Tuesday, May 21

Chadwick Lecture (at the London School of Hygiene and Tropical Medicine, Keppel Street, W.C.1), at 2.30 p.m.—Prof. S. P. Bedson, F.R.S.: "Human Virus Infections of Animal Origin, their Mode of Spread and Control".*

Royal Institution, at 5.15 p.m.—Dr. L. H. Lampitt: "The Manufacture, Preservation and Distribution of Food".*

Thursday, May 23

Society of Chemical Industry (Chemical Engineering Group) (at the Waldorf Hotel, Aldwych, W.C.2), at 6.45 p.m.—Twenty-first Annual General Meeting.

Friday, May 24

Royal Astronomical Society, at 4.30 p.m.—Discussion on "River Flow". (Opening paper by Capt. W. N. McClean.)

Association of Special Libraries and Information Bureaux (in the Lecture Hall of the Science Museum, South Kensington, S.W.7), at 5 p.m.—Discussion to be opened by Dr. L. Newcombe on "The Accessibility of Thesis Literature". Discussion by Dr. J. N. Goldsmith on "Errata and Corrigenda".

Royal Institution, at 9 p.m.—Prof. L. C. Martin: "Ultra-Violet and Electron Microscopy".

Saturday, May 25

British Psychological Society (at 55 Russell Square, W.C.1), at 3 p.m.—H. W. Durant: "A Critical Account of Public Opinion Measurement".

At 5.30 p.m.—J. G. W. Davies: "Individual Differences between Psychological Workers".

At 6.15 p.m.—Alec Rodger and Patrick Slater: Report on "Some New Non-verbal Tests".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Mathematics—The Principal, Science Department, Technical College, Kingston-upon-Thames (May 21).

Headmistress of the County School for Girls, Gravesend—Mr. W. A. Clench, Bank Chambers, Windmill Street, Gravesend (May 25).

Lecturer in Plant Pathology and Zoology—The Principal, Horticultural College for Women, Swanley, Kent (May 31).

Assistant Instructress in Domestic Fruit and Vegetable Preservation—The Secretary and Registrar, Department of Agriculture and Horticulture (University of Bristol), Long Ashton (May 31).

Principal of St. Mary's College (for Women) (University of Durham)—The Secretary, Durham Colleges' Office, 38 North Bailey, Durham (May 31).

Administrative Assistant—The Director of Education, Lindsey Education Office, County Offices, Lincoln (June 1).

Headmaster of Wellingborough College—The Clerk to the Governors, 1 High Street, Wellingborough (June 1).

Lecturers (two) in Civil and Mechanical Engineering subjects, and a Lecturer in Electrical Engineering subjects—The Secretary, Northampton Polytechnic, St. John Street, E.C.1 (June 10).

Lecturer in Botany at the University of Cape Town—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (June 29).

Teacher of Physics at the Rugby College of Technology and Arts—The Principal and Organizer of Further Education in Rugby, 61 Clifton Road, Rugby.

Director of Education—The Town Clerk, Town Hall, Salford 3.

Engineer for the Malayan Postal Service—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9113).

Charge Engineer for the Electrical Department of the Federated Malay States—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9018).

THE CONFLICT

> "Arm yourselves, and be ye men of valour, and be in readiness for the conflict, for it is better for us to perish in battle than to look on the outrage of our nation and our altars. As the will of God is in Heaven, even so let Him do."

WITH this quotation from I Maccabees, iii, 58–60, Mr. Winston Churchill closed his first broadcast message since he became Prime Minister. In calm and dignified terms, he outlined the position in the great battle raging across Belgium and into a corner of France. At the time of writing, the battle is continuing, and on it, the first since the War of 1914–18 in which the German armies have met major Allied forces, depends much of the future course of hostilities. But even if this battle goes against us, still the struggle must continue, for, in the Prime Minister's words, it is a "struggle for life and honour and freedom to which we have vowed ourselves".

Now is the moment when the utmost effort must be made. Thanks to the conquest of the air, it is possible for the leaders of the Allied nations to keep in close personal touch, and to devise immediately ways of meeting the German menace from whichever direction it may come; though equally it may be urged that the progress of aviation and radio communication has made possible the onslaught of masses of tanks and other armoured vehicles, and the wholesale bombardment of hundreds of towns in the invaded countries. The answer surely is that force must now be met with force. After years of endeavour, it must be admitted that the principle of settling disputes by negotiation has not been accepted; the world was not ready for it. The task of educating mankind for peaceful progress has received a grievous setback. Nationalism, at first a puny weakling, has grown, passing through the stage of economic sufficiency of the national unit, until now its chief exponent is aiming at domination of Europe and of the world, by utilizing to the full the fruits of scientific and engineering developments.

To meet the menace will require our whole effort. The immediate need is for more tanks, more aeroplanes, more munitions, to replace the ghastly wastage which is going on. Those whose duties are in this field will not fail the cause. But behind these workers must be an army, ever watchful, ever ready, to find ways of defeating new devices of the enemy and also to seek means of increasing the striking power of our Fighting Services. The interests of pure science and the pursuit of knowledge for its own sake must temporarily remain in abeyance. The whole of the intellectual power of Great Britain must be brought to bear on the task of winning the War. Mr. Duff Cooper, the new Minister of Information, broadcasting on May 18, compared Germany with "a mad gambler at roulette, who has gathered all her vast resources and staked them upon red". It is well to bear in mind that Germany has indeed vast resources, in men, in material and in intellect, and her present rulers will exploit them all to the utmost. To meet this appalling menace will test our powers, but not beyond their capabilities.

Great Britain is now represented by a Government including men of most shades of political opinion, and its constitution under Mr. Churchill has been welcomed from all over the British Empire. France also has a Government formed on a wide basis. The two Empires are united in their determination to rid Europe of the tyranny which has come out of Germany. The battle is joined, and the enemy has shown us the importance of speed and efficiency. Yet more speed and efficiency must be our watchwords in the task before us.

INTERNMENT OF ALIEN SCIENTIFIC WORKERS

IN his broadcast address to the nation on May 19, the Prime Minister emphasized that "there will be many men and women in this island who when the ordeal comes on them, as come it will, will feel a comfort, and even a pride, that they are sharing the perils of our lads at the front. . . ." It would be foolish for anyone to ignore the imminence of such peril, and criminal not to anticipate it with the utmost rigour. In the present circumstances, men of science in Great Britain, whether British, naturalized or alien, cannot expect to be shown any form of preferential treatment.

We have made a few random inquiries and find that certain aliens (research workers, academic staff and students) in those universities which are already included in the areas announced for special treatment have been interned. It seems impossible that any man of science, no matter what his political or other views may be, could, in the extremely grave circumstances and in view of the amazing revelations concerning the activities of 'fifth columnists' in other countries, take exception to the internment of alien scientific workers and students. Many have established themselves as first-rate scientists, and a glance through the correspondence columns of NATURE will reveal that they have contributed much to the advancement of science while resident in Great Britain. Yet there can be no reason for assuming that there are no dangerous elements among such men of science, any more than among other types of alien refugees. One communication in reply to our inquiry, however, states: "I feel that there is little case for interning *bona fide* pure research scientists. The numbers of such intellectual workers would surely be too few to affect matters." To this one might fairly ask, what is the minimum number below which such people would prove ineffective, and are we always absolutely certain of an alien's *bona fides*, scientific or otherwise.

On the other hand, another well-known man of science, in response to our inquiry, pointed out that "the problem of lightening the hard lot of the innocent without assisting the fifth column is not a particularly easy one". Still more pointed is the remark from a third reply that: "The attitude of people at this University *who have been interned* is that the measure is obviously good from the country's point of view and they accept the matter philosophically." This contributor continues, "I think NATURE should hesitate before making any kind of *general plea for release of scientific people* who happen to be interned . . . there is always the possibility that some may be more interested than they seem to be in Nazi Germany, and the *first thing at the moment* is the safety of this country from all possible aspects." The contributor first quoted, however, after pointing out that there is little case for interning *bona fide* pure research scientists, continues: "I am sure it would be an excellent thing not only for general human standards, but also for our national war effort's efficiency, if NATURE were to take the whole matter up."

There is no question, in our view, of "general human standards". We know, from inquiries, that those interned are well treated, and some may even be released again soon. We doubt if the internment of these men of science will affect very much our *immediate* "national war effort's efficiency", and we dare to say that any such loss to science is far outweighed by the all-important elimination of risk.

NATURE has striven hard for intellectual freedom in thought, word and action, but now we are seriously up against "evil things". Unity in a common cause must be kept paramount at present. We have attained it, and it is with pride that NATURE directs attention to the brilliant contributions to our war effort that many of our men of science are making in the Fighting Services and research organizations immediately connected with them, to say nothing of the many scientific workers carrying on at the home front. That unity must be preserved until victory is won. No risk is too great in our efforts to preserve it. The activities of the 'fifth column' have revealed to us what subversive potentialities exist in many countries for upsetting whatever unity of purpose has been achieved. Most men of science, therefore, while undoubtedly feeling sympathetic towards our alien scientific guests, must, on the other hand, consider that any form of preferential treatment for scientific workers in this connexion would carry with it a grave element of risk which cannot be justified.

THE PROGRESS OF PHYSICS

Reports on Progress in Physics
Vol. 6. General Editor : J. H. Awbery. Pp. v+434. (London : The Physical Society, 1940.) 22*s.* 6*d.* net.

IT seems curious to contemplate that there are many physicists to-day, well below 'retiring age', who, like myself, began their study of physics under the fond delusion that, sooner or later, they would become masters of their subject. Physics, even then, comprised a considerable body of information, but not more than a student of reasonable ability and not unreasonable diligence might hope to have encompassed by the end of his university career. With Maxwell's electromagnetic theory of light as the keystone uniting the twin pillars of electricity and optics, it was felt that the main outlines of the structure of classical physics were firmly and eternally established. There were, of course, a few details to be filled in, and one or two untidy corners to be cleaned up. In particular, rather curious things happened when an electric discharge was passed through a rarefied gas ; but, after all, why *should* one pass an electric discharge through a rarefied gas, except to amuse the children at the end of a Christmas lecture ? It was confidently expected that, before long, some persevering Teuton would collate the whole subject in one stupendous tome, labelled "Physics", and there the subject would stand, logical, beautiful and complete. Alas ! we were soon to discover that, like Alice in Looking-Glass World, it took all the running that we could do to remain in the same relative position with regard to our knowledge of the subject. We have had to reconcile ourselves to the fact that physics to-day is no longer logical, cannot strictly be described as beautiful ('provocative' would be a more appropriate adjective) and seems unlikely ever to be complete.

Volume 6 of the annual "Reports on Progress in Physics" produced by the Physical Society, which has come to hand, and is the immediate cause of these reflections, contains more than thirteen hundred references to original publications, in spite of the fact that, in accordance with editorial policy, only about one third of the whole subject is covered each year. Imagination reels at the enormous output of new knowledge. The most painful diligence is inadequate to cope with it. All that the most industrious of us can hope to do is to cultivate our own corner of the garden, and trust to these invaluable reports to tell us something of what the other fellow is after.

To the physicist who wishes—as which of us does not ?—to have some appreciation of his subject as a whole, these annual volumes produced by the Physical Society are quite indispensable. Criticism in detail becomes both irrelevant and ungracious unless this indisputable fact is kept steadily in mind. Some "Reports" may be better than others, just as (so my younger friends inform me) "some beers are better than others", and in both cases it is probably largely a matter of taste. In the present volume one is immediately struck by the admirable catholicity displayed by the editor in his choice of subjects for report. Everyone realizes that in certain directions physics is advancing with incredible velocity. Reports on the meson, on induced radioactivity, on stellar evolution, the cyclotron, and liquid helium were almost inevitable. They are all definitely 'news', and could not well have been overlooked ; but it comes as something of a surprise to those of us who used fondly to imagine that it was "all in Rayleigh" to discover how much new work has been going on in sound ; and further, that it is possible to report important advances in such standard subjects as heat, fluid motion, and impedance networks. It is impracticable to enumerate all the separate reports (twenty-seven in number) contained in the present volume, but enough has been said to indicate the wideness of the front on which physics is advancing.

Glancing down the list of authors, one gains the impression that this year the Society has been fielding a rather younger team than usual. There are a few names of international repute, but for the most part the editor has relied on what (if the authors concerned will forgive the phrase) might be called "the rising generation". His team has certainly not let him down, but one has the feeling that some of them might perhaps have let *us* down a little more lightly. It is flattering when an expert says, "I shall assume that you know all about my subject up to, say, three years ago", and one is loath to shatter the illusion of omniscience which one has spent a lifetime in fostering. Nevertheless, one would (with M. Jourdain) be greatly relieved if the expert would "kindly proceed on the assumption that one did not know". The difficulty of striking a happy mean between the 'too elementary' and the 'too advanced' can readily be appreciated. It would, however, be a real tragedy should these excellent volumes of reports become too specialized to meet the needs of the average physicist. The specialist can be left to fend for himself.

An unusual postscript to the volume is provided by Dr. D. Owen (whose impending retirement will, we trust, set him free for still wider activities) in the form of an objective account of the teaching of physics in technical institutions. The whole subject of the training of physicists, and the proper relationship of the universities, the technical institutions and industry is one which demands urgent attention as soon as the times permit. The progress of physics and of industry in Great Britain depends largely on the wisdom which can be brought to its solution. At the moment, we can but file Dr. Owen's report for future reference.

In a world up-side down, it is perhaps not surprising that a little of the type in this volume should be found to be suffering from the same complaint. A few of the diagrams might, with advantage, have been re-drawn. It is, however, such an achievement to have produced the volume at all under war conditions that one must not be critical. Let us hope that nothing will occur to prevent the appearance in due course of its successor. All physicists will await it with eager anticipation.

J. A. CROWTHER.

HOW WE THINK AND WHY

The Nature of Thought

By Prof. Brand Blanshard. (Library of Philosophy). Vol. 1. Pp. 654. Vol. 2. Pp. 532. (London : George Allen and Unwin, Ltd., 1939). 32*s*. net.

PROF. BLANSHARD is here exploring the debatable and largely unoccupied territory which lies on the borders of psychology, logic and metaphysics. His book might almost be described as a dissertation on the meaning of the prepositions 'of' and 'about' as they are used when we say we are aware of something or think about something. The author is a follower of Bradley and Bosanquet. As their point of view is not very popular at present, it is useful to listen to one who is a persuasive advocate of it and an acute critic of other views put forward recently by British and American philosophers and psychologists. He is clear and forcible in expression, as was Bradley, but more temperate. He is thorough in his treatment, as was Bosanquet, but not so difficult.

The first volume is concerned with perception, as the lowest stage of thought, and with ideas, thought freed from its primitive dependence on perception. The author reviews and criticizes the old image theory of ideas, the Behaviourist theory, those of the Pragmatists and various kinds of Realist, and then gives Bradley's view and his own very similar one. "Looked at from without," he says (p. 563), "the idea is seen to be approximating to its object ; looked at from within, it is seen to be evolving toward definition and concreteness. And the two ends lie in line. To become more concretely defined is to approximate to the object, here and everywhere. The aim of thought is to fulfil itself in the reality." He then develops the intriguing but difficult doctrine of his school that aims at obliterating the distinction between particulars and universals, and replacing the notion of the abstract universal by that of the concrete universal.

In the second volume there is first a very interesting discussion of the mental processes of reflection, observation and invention or creative thinking. Then follows one on the nature and tests of truth. The author maintains that coherence is the unique test of truth and is also descriptive of its character. Like other advocates of the coherence theory, he does not seem to meet quite fairly the objection that there might be many systems of truths, each internally coherent and yet incompatible with each other, like the non-Euclidean geometries. This leads him to undervalue what can be said in favour of self-evidence as the test of truth, in favour of the correspondence theory and even of the despised theory that truth depends on authority. That is to say, if thought is not simply to be chasing its own tail, there must be a starting-point in something immediately intuited. Again, thought appears to be of something which is not itself thought but rather an object for thought. The authority theory emphasizes, however mistakenly, the important point that truth is arrived at by a social process and that there exist experts who are less likely to be wrong than those who are inexpert.

The concluding discussion raises two most awkward problems; the problem of external and internal relations and the question whether the notion of cause implies that of logical necessity. The author argues that ultimately there are only internal relations, which implies, of course, that strictly speaking space and time are illusory. He makes, incidentally, some good criticisms of Logical Positivism.

A. D. RITCHIE.

THE OLDEST KNOWN FOSSIL INSECT

By D. J. Scourfield, I.S.O.

On January 18, I gave a detailed account, before the Linnean Society of London, of further specimens of the oldest known fossil insect.

It is still a quite commonly accepted belief that there is no authentic record of fossil insects from rocks earlier than those of the Carboniferous period. Since 1926, however, there has been good reason to believe that insects had at last been found in Devonian strata. In that year Hirst and Maulik[1] described and figured four heads of a small arthropod, which they named *Rhyniella præcursor*, and which they considered to belong to the Insecta. (The jaw-like structures also referred to by Hirst and Maulik, and afterwards named *Rhyniognatha hirsti* by Tillyard, although possibly belonging to a larval insect, cannot seriously be regarded as a definite record of a fossil insect.) These heads had been obtained from the Rhynie Chert, a siliceous deposit of Middle Devonian age, well known to palæobotanists for its beautifully preserved plant remains, and so called because of its occurrence at Rhynie, near Huntly, in Aberdeenshire.

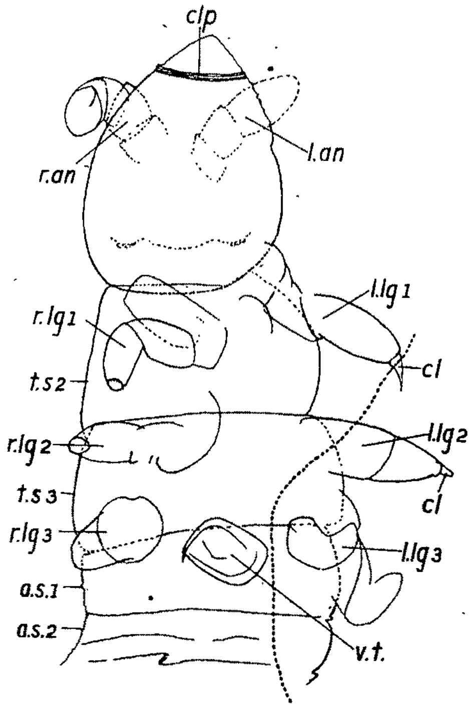

Fig. 1.
HEAD, THORAX AND TWO ABDOMINAL SEGMENTS: WITH ANTENNÆ, PORTIONS OF THREE PAIRS OF LEGS, INDICATION OF VENTRAL TUBE, ETC. DORSI-VENTRAL POSITION. FIGURE VENTRAL. (× 105.)

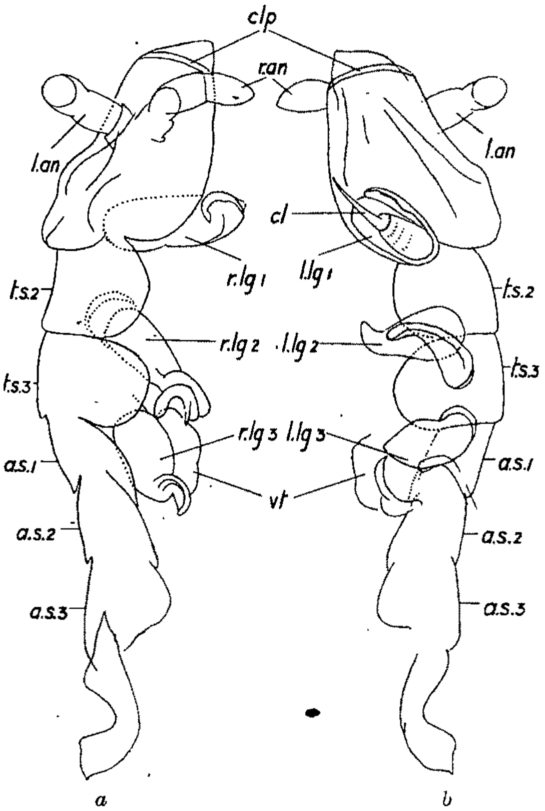

Fig. 2.
HEAD, THORAX AND THREE ABDOMINAL SEGMENTS: WITH ANTENNÆ, THREE PAIRS OF LEGS, ETC. LATERAL POSITION, BUT HEAD NEARLY DORSI-VENTRAL. PROBABLY A CAST SKIN. *a* RIGHT SIDE, *b* LEFT SIDE. (× 105.)

It is true that some doubt has been entertained as to whether these heads were really insectan, but the late Dr. R. J. Tillyard[2], after careful examination of the specimens, was convinced that they belonged to an insect of the order Collembola and might even be of a Podurid type. Coming from such an authority on fossil insects, this opinion seemed pretty conclusive. In view, however, of the great geological antiquity of the Rhynie Chert (some three hundred million years is a modern estimate of the age of the Devonian period[3]) there still appeared to be a possibility that such heads might have been attached to bodies differing somewhat from those of any other insects. This, however, has now been shown not to be the case, and it may therefore be confidently said that Rhyniella was a true Collembolan.

Since the publication of Hirst and Maulik's and Tillyard's papers a number of further specimens of Rhyniella have been found in the same material, mostly by the late Rev. Wm. Cran. These are now in the Geological Department of the British Museum (Natural History), and are described in the current number of the *Proceedings of the Linnean Society*[4], from which the accompanying illustrations are reproduced by courtesy of the Council. Three of the new specimens show heads attached to considerable portions of the bodies (Figs. 1 and 2). It will be seen that the body was elongated, with the segments distinct, thus bringing Rhyniella within the sub-order Arthropleona. They also show that the first thoracic segment (pro-thorax) was without a well-developed tergum, that there were three pairs of legs and that a ventral tube was probably present on the first abdominal segment. No specimen has yet been found with the posterior part of the abdomen intact, and it is impossible to say whether a 'spring' was present or not. The total length of the organism was apparently between 1½ and 2 mm.

Three additional detached heads have also been found, two of which are represented in the accompanying Figures 3 and 4. These heads, while fully confirming the collembolan nature of the mandibles, the conclusion drawn by Tillyard from his examination of the original specimens, also indicate that some at least of the other structures to be found within the head of a recent Collembolan (maxillæ, lingua, etc.) were present in Rhyniella, and further that the animal was provided with ocelli comparable with those of many recent forms.

As was pointed out by Tillyard, the antennae of Rhyniella were typically Podurid, but the absence of a tergum on the pro-thorax indicates affinity with the Entomobryidæ, so that the position of the animal would appear to be intermediate between the two families into which the arthropleonid Collembola are usually divided. This, however, is not a point of very much importance. The remarkable fact is that in all essentials Rhyniella was so similar to modern Collembola that, so far as can be seen, it throws no light even upon the affinities of that group to the other orders of Apterygotan insects, let alone upon the origin of insects generally. What it does certainly show is that the origin of the Collembola, and presumably of Apterygotan insects generally, must have been very much earlier than Middle Devonian.

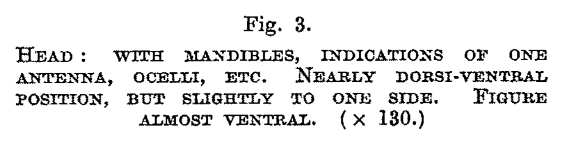

Fig. 3.

HEAD: WITH MANDIBLES, INDICATIONS OF ONE ANTENNA, OCELLI, ETC. NEARLY DORSI-VENTRAL POSITION, BUT SLIGHTLY TO ONE SIDE. FIGURE ALMOST VENTRAL. (× 130.)

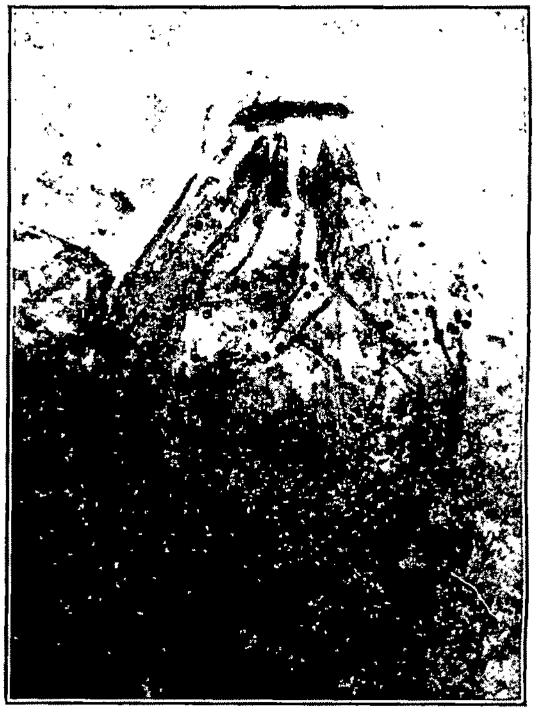

Fig. 4.

HEAD: WITH MANDIBLES, ANTENNÆ, PARTS OF FIRST PAIR OF LEGS, AND MUCH INTERNAL STRUCTURE OF UNDETERMINED NATURE (? MAXILLÆ, ? LINGUA, ETC.). DORSI-VENTRAL POSITION. (× 200.)

Fossil Collembola have so far only been found in three very widely separated geological periods. Before the discovery of the Devonian Rhyniella, the only records were from the Baltic amber of Oligocene age, all belonging to existing genera. Quite recently, however, another form has been found in Canadian amber of Cretaceous age. It has been named by Folsom[5] *Protentomobrya walkeri* and placed in a new family, Protentomobryidæ, intermediate between the Poduridæ and Entomobryidæ, because of the structure of the antennæ on one hand and the absence of a pro-thoracic tergum on the other, as in Rhyniella. It is possible, therefore, that the latter should be included in this new family.

In the discussion following the reading of the paper at the Linnean Society various points of general interest were brought out. Dr. K. Jordan said that entomologists had been convinced, by the study of the morphology of recent Aptera, that these were primitive and not, like lice and fleas, late derivations from winged forms, and now palæontology has confirmed the conviction and turned an opinion into a fact. Dr. F. E. Zeuner thought that the proved occurrence of a specialized group of Apterygotan insects in Middle Devonian material showed that wingless insects were present before winged insects, and that the appearance of the latter coincided with the first forest vegetation on the earth. The earliest tree-like plants were Middle Devonian and it was conceivable that certain Apterygotan insects, which, however, must have been related to the Thysanura rather than the Collembola, took possession of this new kind of habitat and developed wings from lateral pleuræ of the thorax acting as parachutes. Dr. W. T. Calman pointed out the great interest of the glimpse into past conditions afforded by the fortunate discovery of the Rhynie Chert. Prof. F. E. Weiss directed attention to the fact that whereas the plant remains in the Rhynie Chert are of very primitive land plants not directly comparable to any existing groups, Rhyniella can be related to existing Insecta. Similarly in the Carboniferous period, well-developed insects occur comparable to some existing groups whereas the plants are essentially different from recent plants. There seems, therefore, to be a certain lag in the development of modern forms of plants as compared with insects.

THEORIES OF THE LIQUID STATE

By Prof. N. F. Mott, F.R.S.,

University of Bristol

A JOINT meeting of the Physical Society and of the Cambridge Philosophical Society was held at Cambridge on April 29 to discuss the properties of liquids. Among other subjects considered were the problem of melting and also the question of how one ought to calculate the viscosity of a simple liquid. It is extraordinary how difficult these problems are and how little progress has been made with them, especially since, if we exclude the quite exceptional case of liquid helium, it seems very unlikely that quantum mechanics has any bearing on the problems; thus all the physical principles necessary for the investigation may well have been available since the time of Clerk Maxwell. It is not so much the difficulty in picturing what happens when a solid melts, as the difficulty in giving mathematical expression to what happens that holds up progress. In fact, all the attempts at exact mathematical treatment start from models which simplify the phenomenon of melting in such a way that some of the essential features are probably lost.

The problem of viscosity appears in some ways as the most fundamental, because fluidity is, after all, what distinguishes a liquid from a solid, though the distinction is not absolute, since many solids, metals, for example, show creep at high temperatures under small stresses. Andrade[1], in 1934, pointed out that the right order of magnitude for the viscosity could be obtained on the assumption that each successive layer of atoms in the liquid glides over the next, and that each layer transfers all its momentum to the next once in each semi-period of vibration. The vibrational frequencies are taken from the characteristic temperature of the solid, and are assumed to have the same order of magnitude in the liquid. Perhaps the most important advance on this simple theory is that of Eyring[2], who attempts to account for the temperature dependence of the viscosity. Eyring considers that one layer of atoms glides over another only at places where, owing to statistical fluctuations, the density is abnormally low; he expresses this by saying that 'holes' form in the liquid, and estimates from the temperature variation of the viscosity that the size of a hole is about one third of the volume normally occupied by an atom. This point of view makes an interesting contrast possible with the state of affairs in solids; whereas in liquids only a very small departure from the normal structure is necessary for glide to take place, in solids, according to recent theories, a 'dislocation' must be formed, which is a type of discontinuity with considerable energy extending over many atoms. According to Orowan[3], creep is due to the thermally activated motion of such dislocations, and the slow creep rates are due to the large energies of activation involved.

We turn now to the question of melting. One of the oldest theories is that of Lindemann[4], who deduced from the known characteristic frequencies of vibration of the atoms in a number of solids that at the melting points the amplitude of their vibrations was always about one seventh of the interatomic distance. Lindemann suggested that when the thermal vibrations reached this value the solid, so to speak, shook to pieces, and that melting was to be understood in this way. Recently Born[5] has considered the problem from a not dissimilar point of view. Born calculates the elastic constants of a crystal as functions of the temperature, and finds that when a certain temperature T_0 is exceeded, the constant c_{44} becomes negative. The crystal is thus unstable with respect to shear, and, according to Born, must therefore melt at this critical temperature.

While it is certainly true that a crystal for which one of the elastic constants is zero or negative cannot be stable, I do not agree that T_0 represents the melting point; the crystal will melt when the free energy $E - TS$ of the solid phase is just equal to that of the liquid. This will occur when the energy E required to break up the crystal into the disordered state, which is equal to the latent heat, just balances the entropy gained by the same process. At the temperature T_0, since there is no resistance to shear, the former term should vanish and there should be no latent heat[6]. Thus the crystal will actually melt at a temperature below T_0. A similar criticism can be applied to all theories which attempt to derive the melting point from the properties of the solid alone; they give only an upper limit for the melting temperature, and to obtain a complete theory the free energy of the liquid must be calculated as well.

The great difficulty here is that, in spite of many attempts[7,8,9], no satisfactory calculation has been made of the entropy S due to the departure of the liquid from the crystalline state. Eyring[7] has suggested that S should be equal to $k \log(N^N/N!)$, which is equal to Nk, where N is the number of atoms, but his arguments have been criticized from a number of sides[10]. I have made[8] a very tentative estimate of the entropy by regarding a liquid as a polycrystalline solid with very small crystal size and calculating the entropy due to the random orientation of the individual crystals. One trouble here is that we do not know how large to take the individual crystals.

If melting is to be regarded as the break-up of the single crystal into some disordered form, we have also to inquire why this disordering takes place at a definite temperature, and not over a range of temperature. Several workers recently[9,11] have been impressed by the similarity between the phenomenon of melting and the order–disorder transitions in alloys. In transitions of this type, although there is in general a sharp transition temperature and a latent heat, the disordering process always begins below the transition temperature. Lennard-Jones and Devonshire[9] have given a theory of melting in which atoms of the solid are supposed to leave their normal positions as the temperature is raised and to go into interstitial positions; at a critical temperature the distinction between normal and interstitial positions is lost, and the lattice breaks up. In this theory, then, the disordering process does begin below the melting point. The theory is applied quantitatively to the solid rare gases; for other solids, however, it can scarcely provide a correct physical picture of melting; in ionic crystals, for example, the activation energy required to bring an ion into an interstitial position is known from the ionic conductivity[12,13], and in metals it can be estimated from the coefficient of self-diffusion. The activation energies are much too large, and in any event the formation of an appreciable number of interstitial atoms before melting would lead to very large anomalies in the specific heat.

If one considers melting as a break-up into a polycrystalline form, perhaps a more plausible picture can be presented, though it does not seem possible to give it any mathematical justification. To take any little piece of the solid in the interior of a crystal and to turn it round so that it has a random orientation will obviously require a good deal of energy; although in principle such displacements may occur below the melting point in a solid, their number will be very small. When, however, *every* little piece of the crystal has been twisted round in some random way, we can well imagine that the work required for each piece is an order of magnitude smaller, just as it is easier to displace a brick when it is one of a heap piled up at random than when it is built into a wall. But arguments of this kind are perhaps unworthy of an exact science, and the theory of liquids badly needs their replacement by some powerful mathematical methods.

THE COLOURING OF SIXTEENTH-CENTURY HERBALS

BY DR. AGNES ARBER

IN many copies of sixteenth-century herbals the woodcuts are coloured, but we have little direct information as to when, and under what conditions, the painting was done. For this reason it may be worth while to direct attention to certain points which seem hitherto to have escaped notice in connexion with the colouring of one of the most beautiful of these works—"De historia stirpium" by Leonhart Fuchs, published by Isingrin at Basle in 1542. In the description of maize (Cap. cccxviii) the following words occur: "Haec [pictura] in una vagina quatuor tibi granorum colores monstrat, cum tamen quaevis unius duntaxat coloris grana, nempe aut lutea, aut purpurea, aut rufa, aut subcandida omnia habeat. Quod nos, ne aliquem pictura deciperet, monendum esse duximus." This careful explanation that the grains are indicated in four colours—yellow, purple, reddish, and whitish—in one cob, though these variants would not, in fact, be found together, shows clearly that coloured copies must have formed an integral part of the edition, for Fuchs's words would be meaningless if the whole edition had been issued uncoloured.

In painted copies in the libraries of Winchester Cathedral, and of the Linnean Society*, the four colours which Fuchs mentions in the text are represented in horizontal zones in the one maize cob in which the grains can be seen. In similar coloured copies in the University Library, Cambridge (Sel. 2. 81), and in the Library of Corpus Christi College, Cambridge, there is also an attempt at zoning, though the pigments are less well defined. I find, on comparing the general colouring of the two latter copies, that they show certain other points of agreement. For example, both in "Endivien" (endive) and in "Wegwart" (chicory) several flower-heads are shown in blue, while one is indicated in white. This is consistent with Fuchs's descriptions, in which it is noted that both these species are sometimes white-flowered (Cap. cclxii).

A more remarkable case is that of the woodcut called "Lamium" (Cap. clxxvi). It is a composite figure consisting of three shoots growing from a common base, and according to Fuchs's statement, these shoots are intended to represent the yellow archangel, a purple dead-nettle, and the white dead-nettle. In the two copies under comparison, the flowers are distinguished in hue in accordance with the description, and the intention of Fuchs's tripartite picture is thus fully carried out. Moreover, the arrangement is identical in the two copies, the three shoots having yellow, pinkish-mauve, and white flowers, in the order from left to right. In the picture of "Prunus sativa", again, in both copies the tree is so painted as to have yellow plums to the left, blue in the middle, and pinkish-red to the right. Furthermore, in the picture of "Rosa", in both copies the left hand shoot bears white flowers, while those to the right are red.

These examples of accordance in individual details between the colouring and the text, and between different coloured copies, make it probable that the author to some extent controlled the painting. We know that uncoloured copies were also issued, for many of them have come down to us in the untouched state, and some are said to have been painted afterwards by their owners. It is scarcely likely, however, that an amateur, doing the work for his own pleasure, would have taken the trouble to follow out the peculiarities and idiosyncrasies of the text so accurately as has been done in the examples here cited. In the Cambridge University Library copy it is noticeable that the painting is better in its general scheme than it is in the detail, which has a certain rough, mechanical look, which might result from the colourist having to deal rapidly with a number of copies; this is not the kind of imperfection that one would look for in the work of an owner-artist.

Curiously enough, we happen to know something of a much later occasion on which the woodcuts from "De historia stirpium" were coloured before they were sold. In 1774, more than two hundred years after Fuchs's death, a certain Salomon Schinz, who had somehow obtained the blocks cut for Fuchs's herbal, used them to illustrate a book published at Zurich under the title of "Anleitung zu der Pflanzenkenntniss". He had the woodcuts coloured by the children of an orphanage—an economical method of producing *éditions de luxe*, which was apparently not unusual in the eighteenth century. It is pleasant to find that Schinz gives full credit to the orphans, whom he praises in his preface for the pictures, "Durch Euch, liebe Knaben, in Farben dargestellt".

Turning again to the sixteenth century, we may recall Dr. Sprague's crucial discovery[1] that a study of the painted copy of Otto Brunfels's herbal of 1530—"Herbarum vivæ eicones"—belonging to the Kew Herbarium Library, makes it probable that the original water-colours by Hans Weiditz, who illustrated the herbal, were used as patterns for the colours. This view would imply that the Kew copy was painted before it left the publisher's office.

---

* For information on this point I am indebted to the librarians of Winchester Cathedral Library, and of the Linnean Society.

The pieces of evidence so far considered are based on a study of coloured copies of the two primary German herbals of the Renaissance. In addition, we already possess evidence of a more factual kind, derived from the records of a great printing house—that founded by Christophe Plantin of Antwerp, who published the herbals of the 'triumvirate' of Low Country botanists—Dodoens, de l'Écluse, and de l'Obel. M. Bouchery, of the Museum Plantin-Moretus, kindly informed me by letter in 1938 that, in the Plantin Archives, numerous references occur to three women who were employed to colour herbals. These were Lisken Zegers; Myncken, the widow of Hans Liefrinck; and Lyncken, the widow of Abraham Verhoeven. Any student, to whom the original documents at Antwerp are accessible, might be able to unravel the exact part played by these painters in relation to the authors, and to the other artists who were members of Plantin's staff.

To sum up, we may say that the evidence here considered suggests that the colouring of sixteenth-century herbals by individual owners was less frequent than has often been supposed; it can indeed have happened but rarely that an amateur was capable of carrying so onerous a task to completion. There seems more probability in the alternative that the colouring was as a rule done officially before the books were sold. If further study shows this view to be of general application, it means that coloured copies deserve more attention than has hitherto been accorded to them, since they may prove to provide an authoritative commentary on the text, and to emphasize the intentions of the author.

---

OBITUARIES

Prof. Wilhelm Dörpfeld

We regret to record the death of Prof. Wilhelm Dörpfeld on April 26, at the age of eighty-six. Born and educated at Barmen near Düsseldorf, Wilhelm Dörpfeld studied architecture in Berlin, and in 1877 was called from the Prussian Board of Works to be architectural assistant to Dr. Adler at the excavations of the German Archaeological Institute at Olympia, and in 1878 he became technical director. From Olympia he went to help Schliemann at Hissarlik, and collaborated in his publications "Troy" (1884) and "Tiryns" (1886). In 1883 he had married Adler's daughter, and in 1886 he became architectural adviser to the German School in Athens; and in 1887 its 'first secretary', that is, director. After Schliemann's death in December 1890 he continued his work at Hissarlik, revealing the significance of the 'Sixth City' in his "Troja 1893", and reviewing the whole series of discoveries in "Troja und Ilion" (1902).

Meanwhile at Athens he devoted himself to topographical and architectural problems, propounding some original views about the early water supply, and the ground plan of the Erechtheum and Propylaea. He gave remarkable open-air lectures on the sites, and conducted annually a large party of students through Greece, and later also through the islands and to Crete. In 1896, he published, with the philological aid of Reisch, his revolutionary book "Das Griechische Theater", contending that, in the earlier drama, actors spoke not from a raised stage but on the same level as the chorus. After much controversy, this is now generally accepted, though there may be doubt as to the date when the raised platform came into use and assumed the name of the original back-scene (*skenê*).

On the discoveries of prehistoric civilization in Crete, from 1900 onwards, Dörpfeld supported vigorously, but with insufficient local study, the conjecture of Koehler, his predecessor at Athens, that an Aryan culture could be distinguished from a pre-Aryan in the Ægean.

From 1905, Dörpfeld spent much time in excavation in Leucas, which he claimed as the Homeric Ithaca; but neither his rendering of the topography, nor his theory of a general southward shift of island names, nor his archæological finds, have availed to establish the views embodied in "Alt Ithaka" (1927), nor his defence, in "Homer's Odyssee" (1924), of the notion of Helbig that the 'Mycenaean' civilization was of Phoenician origin, and of Conze that the primitive Hellenes practised 'geometrical' art.

After his retirement from the Institute in 1912, Dörpfeld lived in Germany, and held an honorary chair of archæology at Jena; but he frequently returned to Greece, and even excavated at the reputed 'Pylos' of the "Odyssey", and in the prehistoric subsoil of Olympia. Latterly he spent much time in his beloved Leucas, and here he is buried in a tomb prepared by himself overlooking the sea of Odysseus.

Always robust, Dörpfeld was a distinguished figure at the International Archæological Congress so recently as, August 1939. He will be remembered with affection for his remarkable powers of exposition, his gift of inspiring friendship and enthusiasm for his views, his tenacious defence of ingenious theories; but above all for his simple open nature and his delight in the scenes and studies to which he devoted his life.

JOHN L. MYRES.

Dr. C. Davison

With the passing of Dr. Charles Davison on April 28, at the age of eighty-one, at Cambridge, seismology has lost another link with the great pioneers of modern seismology which include the names of Mallet, Milne, Knott, Oldham, Omori, Imamura, Davison and others.

Born on May 1, 1858, at a time when Milne was about seven years old, Davison was the second son of Fleet Paymaster E. C. Davison, and was educated at Armstrong College, Newcastle-on-Tyne, and at Emmanuel College, Cambridge. He spent much of his life as mathematics master at King Edward's High School, Birmingham, and was the author of "Higher Algebra" and "Subjects for Mathematical Essays".

Davison's writings on earthquakes covered a very wide field, including standard and popular books, numerous technical papers and popular articles. He was the leading authority on British earthquakes, 1,191 of which, ranging over a thousand years, he dealt with in his book "A History of British Earthquakes". He had also described the Hereford earthquake of December 17, 1896, and written "A Study of Recent Earthquakes". In 1921 he completed his "Manual of Seismology" and later wrote books on "Great Earthquakes" and "Studies in the Periodicity of Earthquakes".

Since the time Milne was professor of geology and mining at Tokyo, Davison was continuously interested in Japanese earthquakes and Japanese seismologists, some of whom visited him in England. He was the author of the book on "The Japanese Earthquake of 1923" and has written shorter descriptions of many other Japanese earthquakes. The subjects of Davison's scientific and technical papers printed by the seismological societies of many countries, and contained in many geological, philosophical and other periodicals, covered descriptions of individual earthquakes, the history of seismology, velocities of seismic waves, sea waves arising from earthquakes, earthquake sounds, earthquake-recording instruments, earthquake distribution, deep-focus earthquakes, twin earthquakes, volcanic earthquakes, earthquake intensity scales for drawing isoseismal lines and others, the list being by no means exhaustive. To all these subjects he added something of importance. Should it ever become possible to predict the exact time, place and energy of an earthquake, precautions could be taken in advance and many lives and much property saved. Davison no doubt always had this in mind, since on July 31, 1930, he contributed an article to *The Times* on "Earthquakes and Human Life", and he has frequently since 1891 returned to his task of attempting to find any periodicities there may be in the occurrence of earthquakes. He often had occasion to consider the origin of earthquakes, and in 1887 contributed a paper to the *Philosophical Transactions of the Royal Society of London* on "The Distribution of Strain in the Earth's Crust resulting from Secular Cooling", to which G. H. Darwin added a note. For forty-six years, until shortly before his death, Davison was a frequent contributor to Nature on seismological topics.

Before the days of self-recording seismographs Davison did many experiments with pendulums, and often vividly recalled the times when, between two days work, he frequently sat up all night watching his instruments, occasionally being rewarded by the thrill of seeing them move, due to the action of waves from a distant earthquake. For many years he was secretary of the British Association Earth Tremors (now Seismological) Committee, and on the occasion of the recent visit of the Association to Cambridge in 1938, Dr. F. J. W. Whipple and I visited him at his home. Unfortunately, on account of his age, Davison did not feel equal at the time to attending the meetings. He was passionately fond of music and literature, and had an excellent library of gramophone records of Beethoven's works. On March 19, 1934, *The Times* published an article by him on "Robinson Crusoe's Earthquake".

In 1886, Davison married Margaret Blanche Harris, of Great Chart, Ashford, Kent, and had a son and two daughters. E. Tillotson.

I first met Dr. Davison in 1902, when I joined the staff of King Edward's School, Birmingham. At that time the mathematical teaching of the School was under the guidance of a very distinguished teacher, Mr. Rawdon Levett. In the summer of 1903, Dr. Davison succeeded him as senior mathematics master. He made little or no changes in the organization of the teaching, and during the next twelve years a steady stream of able mathematicians passed from the School to the universities. Among them were the last two Senior Wranglers.

Dr. Davison was a tireless worker with a wonderful mastery of detail. He always made use of odd times. Much of his literary work was done in his class room between morning and afternoon school, when other members of the staff would be chatting in the common room. One at least of his many books was entirely written in this way. The report of an earthquake made him very busy, and one of his last pieces of work before he retired was, I remember, an investigation into the transmission of sounds due to the Silvertown explosion during the War of 1914–18.

When he retired from scholastic work in 1920, Davison had well prepared the ground for further academic distinctions. I, who had the privilege of succeeding him and carrying on the mathematical teaching of the School, am glad to put on record how much I owe to his inspiration and wise counsel during the years I served under him. C. H. Richards.

We regret to announce the following deaths :

Prof. C. L. Boulenger, professor of zoology, Bedford College, University of London, on May 19, aged fifty-four years.

Mr. W. H. Massey, M.V.O., formerly consulting engineer to H.M. the King, on May 13, aged ninety.

Mr. Roger Smith, formerly electrical engineer to the Great Western Railway, president of the Institution of Electrical Engineers in 1919, aged seventy-seven years.

NEWS AND VIEWS

The Linnean Medallist for 1940

SIR ARTHUR SMITH WOODWARD, to whom the Linnean Medal for 1940 of the Linnean Society was presented at the anniversary meeting on May 24, was a student of Prof. Boyd Dawkins in Owens College. He entered the Geological Department of the British Museum in 1882, and spent more than forty years in that institution, retiring as keeper of the Department. Between 1889 and 1901 he published four volumes of a "Catalogue of Fossil Fishes", based on a personal knowledge not only of the splendid collection in the Museum, but also of all other important series preserved in all parts of the world. It is a unique publication, a survey by one man of the whole material of a group which has provided that solid basis on which all our recent advances of knowledge of this subject have been built.

But Sir Arthur's interests spread beyond fossil fish to fossil vertebrates in general, and he is very widely known for his collaboration with the late Mr. Charles Dawson in the discovery and interpretation of the Piltdown skull. It is generally recognized that his original interpretation of the many difficult problems, of the reconstruction of this skull from its fragments, and of its significance in the understanding of human origin, was nearer the truth than any other of the many put forward all over the world shortly after the discovery. Sir Arthur has added to the vast mass of detailed accurate information about the anatomy of fossil vertebrates which necessarily forms the body of his work, a series of most illuminating discussions of the broader aspects of palæontology in their bearing on the mechanism of evolution, which have commonly taken the form of presidential addresses to scientific societies.

Linnean Society: Crisp Medallist

THE Crisp Award and Medal for 1940 of the Linnean Society was presented to Mr. D. J. Scourfield, in recognition of the importance of his paper on "The Oldest Known Fossil Insect", recently read before the Society and summarized on p. 799 of this issue of NATURE. The Award, which was established in 1912 by a donation from the late Sir Frank Crisp, formerly treasurer of the Society, is given "as a reward for the best paper, dealing with microscopical research by a Fellow, published by the Society since the previous award". By the terms of the donation it is given "at intervals of not less than five years" but, actually, the period has generally been much longer. No doubt it has been found difficult to define the type of research that could strictly be termed "microscopical", since there are few branches of biological work which do not require at least the occasional use of the microscope. In the case of Mr. Scourfield's paper, however, no doubt could arise, since it was only his unusual skill and long experience in microscopical manipulation that enabled him to elucidate so convincingly the structure of these minute and obscure fossils from the Rhynie Chert. He had already done the same for another arthropod from the same deposit, the remarkable crustacean Lepidocaris, described in his well-known memoir published by the Royal Society in 1926. The debt that British biology owes to the work of amateur microscopists has often been pointed out. Mr. Scourfield worthily sustains the tradition of a long line of distinguished predecessors.

Linen Industry Research Association: New Director

DR. A. J. TURNER has been appointed director of research of the Linen Industry Research Association in succession to Dr. W. H. Gibson. Since 1931 Dr. Turner has been head of the Spinning Department of the British Cotton Industry Research Association. Prior to that date, he was for six years director of the Technological Laboratory of the Indian Central Cotton Committee, Bombay. He has also held the posts of head of the Experimental Fabrics Section of the Royal Aircraft Establishment and professor of textile technology in the Manchester College of Technology and in the University of Manchester. Dr. Turner takes up his duties at Lambeg, Northern Ireland, on September 1 next.

Fauna and Flora of the Low Countries

THE intense fighting over such a wide area of the Low Countries also threatens to damage fauna and flora of international interest, as in Norway (see NATURE of April 27, p. 663). In Holland there are well-known sanctuaries for seabirds that have attracted photographers from Britain for many years, and the Netherlands Society for the Protection of Birds has done much to preserve the breeding haunts. The sandy island of Texel near the Zuyder Zee is the breeding ground of many former British breeders which have now left their British nesting haunts. The black-tailed godwit is common on the polders, as are nesting ruffs at Wall en Burg polder, avocets, Kentish plovers, a few pairs of black tern nest, and of blue-headed wagtails, icterine and marsh-warblers, Montague's and marsh-harriers and spoonbills at the inland lake of Muy, garganey, short-eared owls and various commoner species. Texel is preserved under the State Forestry Commission. Another Dutch preserve, the Naardermere, has bitterns, ruffs, black terns and marsh-harriers. In winter the country is a great haunt of wild duck, and 140 duck decoys take 300,000 a year for the canning industry.

In Belgium, the Yser estuary is a reserve for waders, wild-fowl, etc., and there is another wild-fowl sanctuary near Nieuport. These were under the Ministry of Agriculture. Interesting experiments have been made with the successful introduction of the Scottish red grouse. The Flanders dunes have a very interesting flora, in many ways like that of the dunes of South Wales, western Lancashire or Norfolk. In the wet dunes and pools grow grass of Parnassus, round-leaved wintergreen, purple loosestrife, hemlock, storksbill, and on the dry ones, toadflax, bird's-foot trefoil, creeping willow, pink centaury, squinancy wort, burnet rose, Chinese box thorn, evening primrose, musk orchid, marsh helleborine, etc. The alien evening primrose on the Dutch dunes is associated with the important researches of de Vries and the doubling of chromosomes in *Œnothera Lamarckiana*. The famous Flanders poppies, increased by the calcareous nature of the soil following the bombardment of buildings in the War of 1914–18, had declined in numbers in recent years as the soil had returned to more normal type.

The Food Industry in War-time

In a lecture at the Royal Institution on May 21 in the series "The Nation's Larder", Dr. L. H. Lampitt, director and chief chemist of Messrs. J. Lyons and Co., Ltd., discussed "The Manufacture, Preservation and Distribution of Food". The food industry occupies a position between that of catering by households and catering of the canteen type. The economy to be effected by mass production is obvious because wastage is reduced to a minimum ; all waste products are taken and so treated that they have an economic value, labour is reduced and—a very important point—the amount of fuel consumed is considerably less. A striking example is in the baking of cakes. An ordinary gas cooker as operated by a housewife consumes approximately 10 cub. ft. of gas for each lb. of cooked weight of cakes, assuming the housewife was making 4–5 lb. of mixed cakes. In the case of a travelling oven, producing thousands of cakes an hour, the consumption of gas for each lb. of cooked weight is about 1⅛ cub. ft. In the realm of the homely potato, the average housewife loses approximately 22 per cent in peeling and eyeing. In mass treatment, where peeling is carried out by mechanical means, the loss is only 11 per cent.

By far the greater proportion of the bread baked in Great Britain is produced by large mechanical bakeries, and it is not an easy task to change over plant producing loaves made from white flour to loaves made from brown flour. The utilization of edible products not previously generally used as food, or used in a different form, is comparatively simple. Examples are the *Ersatz* coffee of Germany made from roasted barley and the *Ersatz* tea made from mixed leaves and shoots. These make palatable drinks, but the effect on the body is not the same as the natural products. By complicated chemical reactions, oils of the paraffin type which are unabsorbed by the human organism can be transformed into edible fats, and this is probably being carried out in Germany to-day. The production of protein matter by the activity of specially selected strains of yeast was practised in Germany during the War of 1914–18, and factories for this purpose were in being last year.

The Differential Analyser

In the application of mathematics to many problems both of pure and of applied science, rate of change of a quantity is often related to the magnitude of that quantity itself. This situation is expressed formally by a 'differential equation'. The differential analyser, of which the first was designed and built at the Massachusetts Institute of Technology by Dr. V. Bush and his team, is a machine for evaluating by mechanical means the solutions of differential equations, and its main applications are to problems giving rise to such equations which cannot be solved by formal methods.

Prof. D. R. Hartree, professor of theoretical physics in the University of Manchester, described the principles and applications of such a machine in his Friday evening discourse at the Royal Institution on May 17. The machine consists essentially of a number of integrating units each of which is a precision form of continuously variable gear. These units can be interconnected in various ways by shafts and gearing so as to form a translation into mechanical terms of the differential equation to be solved. There is also a number of 'input tables' from each of which information, in the form of a graph expressing the relation between two of the variables in the equation, can be supplied to the machine, and means of recording the solution of the equation either in graphical or numerical form ; there are also adding units each of which can form the sum of two terms in the equation. There are at present seven full-size machines of this kind in operation, and also in Great Britain, several small-scale ones, some built mainly of standard Meccano parts, and others workshop-built. It may be recalled that the differential analyser at Manchester was described by Prof. Hartree in NATURE of June 8, 1935, p. 940.

Summer School in Social Biology

The Educational Advisory Board of the British Social Hygiene Council is arranging a Summer School for Teachers and Social Workers at Westminster College, Cambridge, during August 1–8. The main interest of the School will be focused upon a "School-Leavers' Course in Human Biology" which has recently been prepared by the Educational Advisory Board to assist in meeting the urgent problems that have arisen affecting adolescents as a result of war conditions. Various aspects of the syllabus will be presented in the form of symposia, contributed to jointly by distinguished biologists and practising school teachers. These symposia and the ensuing discussions should be of considerable value in helping participating teachers to a deeper understanding of the natural endowments of their pupils. Another section of the School will deal with some of the problems in social biology which to-day have become a matter of vital concern for the peoples of the British Empire.

Prof. J. C. Ryle, regius professor of physic in the University of Cambridge, will be president of the School, and Mr. L. J. F. Brimble will be director.

The inaugural address will be delivered by Sir Walter Langdon-Brown, emeritus professor of physic in the University of Cambridge. The following speakers have undertaken to give lectures and take part in discussions: Prof. J. C. Drummond, scientific advisor, Ministry of Food; Dr. Leslie J. Harris, director of the Nutritional Laboratory, University of Cambridge; Dr. Grace Calver, physician, Children's Department, Tavistock Clinic; Mrs. C. Neville-Rolfe, past vice-president, Eugenics Society; Sir Drummond Shiels, medical secretary, British Social Hygiene Council; Mrs. E. J. Hatfield, North London Collegiate School; Mr. R. Weatherall, Eton College; and Miss V. D. Swaisland, British Social Hygiene Council. Further information can be obtained from the Education Officer, British Social Hygiene Council, Inc., Tavistock House South, Tavistock Square, London, W.C.1.

International Relief Union

THE origin, aims, means and future of the International Relief Union are discussed by M. Camille Gorgé in a pamphlet recently issued by the Union (Geneva: International Relief Union). M. Gorgé points out that, for good or for ill, the States of the world have become so closely welded together that they form a great family from which no one member can dissociate himself without serious inconvenience or actual hardship. Although international co-operation has at present lost most of its vitality and force, sooner or later the nations must revert to the method of collective agreements, and use the instruments or machinery already established for that purpose. The International Relief Union, which was established by the Convention of July 12, 1927, was largely the outcome of a scheme elaborated by M. Giovanni Ciraolo to provide not only for immediate and organized relief for peoples overtaken by disasters, such as earthquakes or other catastrophes arising from natural causes, epidemics, famine, etc., but also for the scientific study of the causes of natural calamities, with the view of counteracting or limiting their effects. According to the Convention, the International Relief Union has a fourfold task: it must furnish first aid to the populations that are victims of public disasters, and co-ordinate, as occasion offers, the efforts made by other relief organizations; it must also encourage the study of preventive measures against disasters and seek to induce all peoples to render mutual international assistance.

The Convention did not come into force until December 27, 1932, and its financial resources were too limited for it to do its work freely and effectively. Special stress is laid upon the mobilization of the forces of good will against adversity beyond national frontiers, and upon encouraging scientific men to study how to combat or even counteract future disasters. Scientific workers are urged to co-ordinate research in all its branches so that the various communities may unite their concrete efforts, based on accurate data, to minimize the damage to the human family caused by great scourges. Aviation and broadcasting have already done something to reduce the gravity of certain disasters, and fresh opportunities of foresight and defence continually arise. To assist scientific workers to explain their ideas and compare results in this field, the Union in June 1938 issued the *Revue pour l'étude des calamities*, replacing the *Matériaux pour l'étude des calamities*, previously published by M. Montandon in collaboration with the Société de Géographie de Genève. One of the first tasks of the Union in this field is to make a detailed study of the geography of natural disasters. A resolution of the first International Conference for Protection against Disasters, Paris, September 1937, recommended that the Union should consider the appointment of a Permanent International Committee for Protection against Disasters, collaborating with the Board of Scientific Documentation of the Union, and M. Gorgé briefly indicates directions in which such concerted scientific effort is required.

Wood Pole Transmission Lines

IN order to examine the incidence of risks from shocks and fire due to the use of wood-pole transmission lines, tests were undertaken of primary insulation at 19, 11 and 6·35 kv. The work is described by G. T. Garwood in the *Electrical Review* of April 12. The structure on which the tests were carried out comprised a plain-sawn English oak cross-arm, 5 in. by 3 in., bolted to a red fir-pole, 32 ft. by 11¼ in. in diameter at 5 ft. from the butt. The pole was sound in every way and had been creosoted. The instruments used for the tests were two electrostatic voltmeters. The resistance between the cross-arm bolt and earth was measured on frequent occasions in the period during which the test was being taken and also under varying conditions of dryness. The megger readings ranged from 200,000 ohms with the pole dry to 50,000 ohms with it wet. With the 11 kv. connexions a current of 140 micro-amperes could be obtained from below a plain earthing collar. As 15 micro-amperes may give a fatal shock to a normal man, if his heart lie in the circuit, the experiments showed that a plain earthing collar round the pole is insufficient protection. In the destruction tests, about ten minutes after the wetting of the pole smoke appeared from the cross-arm near the insulator pin. Longitudinal 'shakes' opened up in the cross-arm and showed signs of carbonizing. After about twenty minutes, smoke appeared from these shakes, the source of the smoke moving steadily towards the pole. After thirty minutes, smoke appeared from the pole top and 'tracking' with small intermittent flames at the earthing collar. Heavy smoke and flames appeared at the pole-top after seventy-five minutes and after eighty-five minutes the test was stopped, it being clear that the complete destruction of the structure was inevitable.

Flavour of Bacon

THE Department of Scientific and Industrial Research has issued a report describing work carried out for the Food Investigation Board on the importance of various factors responsible for the pro-

SHORT REVIEWS

ANTHROPOLOGY AND ARCHÆOLOGY

The Discovery of Man

The Story of the Inquiry into Human Origins. By Stanley Casson. Pp. 340+16 plates. (London: Hamish Hamilton, Ltd., 1939.) 12*s.* 6*d.* net.

IT is remarkable, but none the less true, as Mr. Casson points out, that in the order of the development of the sciences man comes last to the most fascinating study of all—the study of himself. It is further notable that the study of man, affording so many avenues of approach, has so frequently, but no doubt inevitably, advanced by the investigation of what may be regarded as side issues. This appears here in the author's references to early developments in ancient and classical Greece, where, for example, the collection of ethnographical and geographical data was an outcome of the needs of navigation and commerce; and if history as conceived in the theory of Herodotus demanded a basis of ethnography, Thucydides turned no less to a line of investigation which was in effect archæological research.

Mr. Casson's entertaining and informative narrative follows the development of the various branches of anthropological inquiry through classical and medieval times and the Renaissance down to modern times. His wide acquaintance with the less-known paths of classical and post-classical literature has enabled him to record much that will be both new and of value to those who are interested in the earlier phases of scientific modes of thought. Coming to modern times, as an archæologist who himself has worked in the field, he is able to survey the record of workers in the various regions of the Mediterranean and the Near and Middle East with a firm grasp of the trend of discovery as a whole, and at the same time a just appreciation of the contribution of each individual investigator in the major fields of discovery.

On the ethnographical side, and in what is now termed cultural anthropology, Mr. Casson is not, it must be admitted, equally well equipped, nor in consequence is his record so complete, especially when he deals with the descriptive and comparative studies in religion and law of English and French writers of the late sixteenth and the seventeenth centuries and the French compendia of races of the early eighteenth century, which led up to Montesquieu.

Escape with me! an Oriental Sketch-Book

By Osbert Sitwell. Pp. xv+340+16 plates. (London: Macmillan and Co., Ltd., 1940.) 12*s.* 6*d.* net.

IT is always of interest to the archæologist to note the reactions of others to the material in which he himself works. If they have the trained eye of the observer of men and cities, a sense of æsthetic values, combined with a gift of literary expression, he may hope to recapture from their observations something of the nature of the general complex of the culture as a whole which it is his purpose to recover from the evidence of the past, but which his preoccupation with details of research too often precludes him from viewing in true perspective. No one assuredly who desires a scientifically accurate account of Angkor or Peking would consult Mr. Sitwell's "Escape with Me" as a first-hand authority, yet from his vivid pen pictures of the line, mass and colour of the great complex of temple monuments at Angkor and his obvious sympathy with Eastern modes of life and thought, especially as lived in Peking, it is possible that the reader may attain a truer understanding than from more solid treatises in the archæological or historical sense.

It must not be imagined, however, that Mr. Sitwell's book, frankly escapist, is the fruit of hurried impression. Some months were spent by him in Peking, his contacts with the Chinese were as intimate as the circumstances allowed; and he made full use of Bodde's translation of "Annual Customs and Festivals of Peking" and Arlington and Lewissohn's "In Search of Old Peking", with results no less pleasing to the reader than gratifying to himself. Thereby in effect he was led to a judgment of Chinese culture and character in relation to current events or which there is much to be said.

BIOLOGY

Textbook of Biology

By Dr. E. R. Spratt and A. V. Spratt. Second edition. Pp. viii+692. (London: University Tutorial Press, Ltd., 1939.) 11*s*. 6*d*.

IN preparing the second edition of this work, the authors have completely revised the original text and figures and have added two new chapters dealing with Pinus and Angiosperms to meet the requirements of the Pharmaceutical Society's examinations. The material presented is intended to cater for students pursuing courses in biology for the intermediate science, pharmacy, and medical examinations of Great Britain, the higher school certificate, the preliminary medical, and other examinations of a similar standard. The greater part of the book is concerned with minute descriptions of the anatomical mechanisms of the plant and animal types met with in these various examination syllabuses. This is followed by a smaller physiological section, which is chiefly concerned with plants, and a chapter on ecology. The laws of heredity and evolution are summarily treated, while the appendix contains useful practical hints. The book is admirably illustrated with a considerable number of clear diagrams. Inaccuracies of the previous edition have been largely eliminated, although it is a little disconcerting still to read that Pellia "is branched to form many lobes, thus reminding us somewhat of the liver of an animal and giving the plant the name liverwort".

This is indeed a text-book and would only be of use as a source, and perhaps better, revision book for the examinations mentioned above. T. H. H.

A Naturalist on Rona

Essays of a Biologist in Isolation. By Dr. F. Fraser Darling. Pp. x+138+28 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1939.) 7*s*. 6*d*. net.

DR. FRASER DARLING'S sojourn on the isolated island of Rona has repaid its hazards, since it gave him the opportunity of writing these essays as well as of observing that unique seal rookery during the breeding season. Many subjects are touched upon in the eight essays, ranging from the archæology of the primitive chapel and cell of St. Ronan, which the author partially restored, to display of birds, social life of animals, animal sanctuaries, and an excellent account of the habits of the grey seal. The essays are vivid in their description, are attractively written and are illustrated by some beautiful photographs. If occasional inaccuracies creep in they are not serious. For example, in his strong plea for the creation of sanctuaries in Great Britain, the statement that "before Theodore Roosevelt's time a few people had thought, rather ineffectually, about the protection of wild life", takes little account of the facts that Congress had set aside the Hot Springs Reservation in 1832, that the Yellowstone National Park was established in 1872, and that the American Ornithologist's Union had its law for the protection of wild birds in 1886, quite apart from much effective legislation in other countries.

A Catalogue of Yorkshire Fungi

By the late F. A. Mason. Completed from the Records of the late Alfred Clarke by Dr. John Grainger. Pp. xii+110. (London and Hull: A. Brown and Sons, Ltd., 1937.) 7*s*. 6*d*. net.

THIS Catalogue of Yorkshire Fungi (Limited Edition) is essentially an extension of Messrs. Massee and Crossland's "Mycological Flora" (1905), which attempts to bring up to date those records, supplemented from forays and individual efforts.

The new volume adds about 835 species and varieties, chiefly in the Basidiomycetes (660) and the Ascomycetes (110) sections. The × and — method of recording is unsatisfactory as it signifies the mere presence or absence of the species in an area of usually more than 1,000 square miles with no indication of frequency or otherwise, so that the old Flora will still be the only reference book giving both species and localities.

Apart from the above and a dateless title-page, the chief fault of the work is its omissions, primarily of sources: thus many species and V.C. records are absent, for example, August 1934 Goole district records have been placed in the East and not West Riding, no mention of Entomophthoraceæ for the East Riding, although seven of these species were listed in the *B.M.S. Transactions* 1932; while *Cordyceps entomorrhiza* is a misnomer for *Cordyceps gracilis*.

The Mycological Committee has reviewed the work and decided to publish amendments in the *Yorkshire Naturalist* that will greatly add to its utility.

J. W. HAIGH JOHNSON.

Tertiary Siphoneous Algæ in the W. K. Parker Collection, with Descriptions of some Eocene Siphoneæ from England

By Lucien and Jean Morellet. Pp. ix+55+6 plates. (London: British Museum (Natural History), 1939.) 5*s*.

CALCAREOUS green algæ (of the Siphonales) are now almost confined to warm seas, but fossil representatives are being discovered widely. This catalogue describes an important series of specimens from a well-known Eocene locality in France, and for the first time some similar ones from England. The study of these fossils has required very close observation of minute specimens (the present collection had been classed as Foraminifera), bold hypothesis and good luck; this last is seen here for Ovulites. This common fossil was known as little shells shaped like a blown bird's egg. Specimens have now been described in which a chain of these are still held in position by the continuous skeleton of an encrusting Bryozoan; the new specimens show that Ovulites is very like the existing alga Penicillus.

The large number of specimens mentioned as *Incertæ sedis* indicate room for further study and further good luck. TOM M. HARRIS.

Bats

By Glover Morrill Allen. Pp. x+368+31 plates. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1939.) 17*s*. net.

THIS book is full of information of value to those specializing in the study of bats; but it is written for the general reader. It seems scarcely possible that anyone except a bat-specialist would want to know so many details about bats, and the innumerable names of different species can mean almost nothing to those who have not made a special study of the group. The biologist with special interest in the Chiroptera will find this a really valuable book written by an enthusiast, but will probably skip the unnecessarily large part devoted to popular superstitions about the order. The same amount of space could more profitably have been devoted to classification, which is scarcely touched upon. Many of the photographs are good. A large and useful bibliography is given.

Ce qu'il faut savoir des insectes

Par G. Portevin. Vol. 2: Coléoptères et hémiptères. (Savoir en histoire naturelle, Vol. 3.) Pp. 308+14 plates. (Paris: Paul Lechevalier, 1939.) 40 francs.

THIS is an excellent low-priced guide to the orders Coleoptera and Hemiptera. It is primarily a pocket manual designed to aid in the recognition of the chief members and, for this purpose, there are numerous keys to families and genera together with notes on some of the more characteristic species. The text-figures are clear and accurate and the plates are good.

CHEMISTRY

Reports of the Biochemical Research Foundation of the Franklin Institute

Vol. 5, 1938–1939. Pp. vii+42 papers. (Philadelphia: Franklin Institute, 1940.)

THIS collection of stimulating scientific publications shows how diverse biochemical techniques, recently discovered in various parts of the world, can be used to supplement one another in the elucidation of particular problems in the attack on disease. Thus in the chemical and microchemical sections the manometric respirometer methods of Warburg and of the Cambridge school together with the Linderstrøm-Lang microtechniques are used to study metabolic and enzymic activities of tissues. The cyclotron is used for the production of radioactive elements which can afterwards be introduced into compounds of biochemical interest, for example, glutathione containing radioactive sulphur. In the physico-chemical and immunological departments, purification and analysis of therapeutic serum antibodies are carried out by the Svedberg ultracentrifuge, and the electrophoretic technique of Tiselius is applied to studies on antibodies from allergic sera.

The Biochemical Research Foundation, which was formerly known as the Cancer Research Laboratories, has now a wider outlook on disease. Its aims are: (1) the study of disease from a chemical point of view; (2) the study of new compounds for their therapeutic and beneficent effects; and (3) the study of age and the diseases of age. Such problems are attacked from their fundamental basis. For example, pancreatic hormones having blood pressure lowering action and their isolation, one of the many lines of research undertaken by the Foundation, may seem to have little to do with the ageing process, but substances which reduce blood pressure, an age manifestation, have a great deal to do with it.

Theoretical and Applied Electrochemistry

By Prof. Maurice de Kay Thompson. Third edition. Pp. xxi+535. (New York: The Macmillan Company, 1939.) 22*s*. net.

THE new edition of this excellent book is entirely re-written, but it preserves all the valuable features of preceding issues. The first part is a compact treatise on modern theoretical electrochemistry which, on account of the concise style, covers all the important branches in a comprehensive and satisfactory way. The second and third parts deal with the applied electrochemistry of aqueous solutions, and with electric furnaces and their products, respectively, and here again the treatment is comprehensive and accurate. The amount of information contained in the book is surprising, and no important branches of the subject seem to have been missed. The literature references are very complete, and the illustrations are clear and well chosen. A particularly valuable feature is the large number of problems and exercises, for which not only answers but also concise solutions are provided. This is a thoroughly satisfactory book, and the author deserves high praise for the skilful and expert way in which he has brought the material together and for the clear and accurate presentation of it.

GEOGRAPHY AND TRAVEL

This Way Southward

The Account of a Journey through Patagonia and Tierra del Fuego. By A. F. Tschiffely. Pp. xvi+354+50 plates. (London and Toronto: William Heinemann, Ltd., 1940.) 15*s*. net.

MR. TSCHIFFELY, who had already won a well-deserved reputation as an adventurous traveller in the Americas on horseback, here records the events of another one-man expedition, though in this instance by car. From Buenos Aires he drove down the Atlantic coast of Patagonia to Tierra del Fuego and thence back to Buenos Aires along the western side of the continent by way of the Andes and across the continent. In all, 7,000 miles were covered, the return journey along the Andes involving a number of detours to avoid country unsuitable for the car. This was, indeed, the most difficult part of the journey, and frequently skirted country which is not only unexplored but also probably unexplorable except by air.

On the outward journey the author visited the famous Welsh colony founded in the middle of the last century, in which in the younger generation knowledge of English has almost completely disappeared. His description of a country which has nothing to offer in the way of the picturesque is none the less of considerable interest in view of the economic development of a territory once regarded as an arid waste. If the outward journey was not without its incidents, the return, starting from the embarkation on the ice-encircled Lake Argentino, provided them in plenty, and from this point also Mr. Tschiffely is able to incorporate in his narrative episodes from the history of the country, beginning with the Conquistadores and the search for El Dorado down to the ill-fated attempt to develop sheep-farming on the Rio Baker. In describing what he saw of Tierra del Fuego the author tells his readers something of the Yahgan and Ona Indians, not as they are now, but as they were at the beginning of the century, his information being derived from Mr. Lucas Bridges, "the only living authority". His own experiences among the Tehuelche Indians, now mostly 'civilized', included visits to some of those who still live in primitive 'tent-villages', but whose life is sadly circumscribed by the loss of freedom of the land.

The Wandering Lake

By Sven Hedin. Translated from the Swedish by F. H. Lyon. Pp. x+293+30 plates. (London: George Routledge and Sons, Ltd., 1940.) 18*s*. net.

"THE Wandering Lake", originally published in Swedish, is the third volume which Dr. Sven Hedin has devoted for the benefit of a non-technical public to the activities of the members of his great expedition to Central Asia. On this occasion he deals with the explorations carried out in 1934, of which the most important from the scientific point of view was the examination of the conditions accompanying and arising out of the change in the drainage of the Tarim Basin, which took place in 1921. In that year the waters draining into Lake Kara Koshan were diverted into an ancient watercourse, the Kum-daria, in which water had not flowed for some sixteen hundred years, to form a lake in the Lop-nor depression. Kara Koshan, discovered by Prjevalsky in 1876–77 and identified by him with the ancient Lop-nor, is now becoming desiccated.

The dry ancient watercourse of the Kum-daria had already been traversed by Dr. Sven Hedin at the beginning of the century, when he discovered the ruined city of Lou-lan, and on the basis of his observations of physiographic conditions, ventured to put forward a hypothesis as to the position of the ancient Lop-nor and the physical conditions making it a wandering lake, which the course of events would now appear fully to justify.

Three years before the journey recorded in this volume, two members of the expedition had explored the delta of the Kum-daria where it enters the lake. Here the author records the events of a journey made by canoe with the object of ascertaining how far the stream was navigable. The story is told with the meticulous attention to detail to be expected from the author, and includes a graphic picture of the lake—a remarkable body of water both in size and character.

MATHEMATICAL AND PHYSICAL SCIENCES

An Introduction to the Calculus

By Prof. K. R. Gungikar. Pp. xiv+341. (London: Oxford University Press, 1938.) 4 rupees.

THIS little volume has been designed as a first course in the calculus for Indian students. The treatment is the outcome of years of experiment and observation and the method followed is, as the author points out, rigorous in the long run. By this is implied that the refinements of modern rigour are gradually developed, as they should be, in accord with the fundamental principles of true teaching. This idea, which is not too frequently apparent in mathematical text-books, as distinct from those written especially for schools, has been well and consistently carried out. After a commendable foreword to the student, twelve instructive chapters follow which should ensure a firm foundation for future study of the calculus. Beginning with limits and continuity, occupying three chapters, the student is led to the derivative itself. The usual standard theorems concerning the differentiation of functions are then considered, together with second order derivatives, maxima, minima and the exponential and logarithmic functions. Integration is next introduced as the inverse of differentiation, its full significance being developed later in accordance with the aim of the writer. The final chapter, after summarizing a few of the more important standard results previously established, proceeds to discuss briefly Taylor's and Maclaurin's series, Rolle's theorem, partial fractions, hyperbolic functions and surface and volume integrals.

The text has been well written and is not only sound but also designed to stimulate the reader's interest. It is excellently illustrated with fully worked-out practical examples as well as with clearly drawn diagrams. Each chapter closes with an appropriate set of exercises for the student, and answers to these are supplied. The book should prove very useful to all mathematical students of this essentially practical subject.

Geometrische Kristallographie und Kristalloptik und deren Arbeitsmethoden

Eine Einführung. Von Dr. Franz Raaz und Dr. Hermann Tertsch. Pp. ix+215. (Wien und Berlin: Julius Springer, 1939.) 18.60 gold marks.

THIS book is suitable for students engaged in a systematic course of formal and optical crystallography corresponding roughly to Part 1 of the Natural Sciences Tripos at Cambridge in those subjects. All the usual and essential features are included, and an introduction to the manipulation of the Von Federow universal stage will be appreciated by the more advanced worker. The knotty question of the real significance of conoscopic illumination is very ably handled, with a clear diagram to correspond.

Whilst nothing very new is to be found in these pages, the reader will probably benefit by using this volume, mainly because the authors present their matter well, and incidentally by reason of the good practice which is obtained by following a well-known theme in a foreign language.

F. I. G. R.

MEDICAL SCIENCES

Medical Microbiology

By Prof. Kenneth L. Burdon. Pp. xii+763. (New York: The Macmillan Company, 1939.) 18*s*. 6*d*. net.

THIS work, which is intended both for students and their teachers, is divided into four parts and five appendixes. The first part, which deals with the fundamentals of microbiology, consists of sixteen chapters, including an account of the historical aspects of the subject, the various types of micro-organisms, their classification and nomenclature, and their destruction by physical and chemical methods. The second part is concerned with the laboratory study of micro-organisms, and gives a description of the apparatus, culture media, isolation of bacteria and the collection of specimens for bacteriological examination. In the third part, which deals with infection and resistance, sources of infection, modes of spread by water, milk and other foods, the part played by insects, natural and acquired immunity, vaccine and serum therapy, and anaphylaxis receive attention. In the fourth part the microbiology of important infectious diseases is studied, including tetanus, diphtheria, pneumonia, typhoid and paratyphoid fever, staphylococcus and streptococcus infections, etc. The appendixes are devoted to a comparison of metric and English scales, formulæ for the preparation of media, reagents and stains, important immunological tests, classified lists of references, and questions to which the answers will be found in the foregoing pages.

This comprehensive work, which is liberally illustrated, will form a useful handbook for the laboratory worker and clinician alike.

Epidemiology in Country Practice

By Dr. William Norman Pickles. Pp. viii+110+1 plate. (Bristol: John Wright and Sons, Ltd.; London: Simpkin Marshall, Ltd., 1939.) 7*s*. 6*d*. net.

THE author, who is medical officer of health to the Aysgarth rural district in Yorkshire, is introduced in the preface by Prof. Major Greenwood in allusion to the Bristol physician and epidemiologist as "a second Budd", which, as the reader will find, is a high, but well-merited, compliment. Dr. Pickles not only appeals to other country doctors to keep records, as he has done for many years, of epidemic diseases, but also seeks to awaken the interest of the layman, whose help in this field he regards as inestimable. The work, which is remarkably readable, consists of a number of essays, some of which have already been published in various medical journals, dealing with certain common infectious diseases, such as influenza, measles, scarlet fever, whooping-cough, mumps and chicken-pox, as well as less common infections, such as Sonne dysentery, pink disease, undulant fever, epidemic catarrhal jaundice, and the disease variously known as epidemic myalgia, Bornholm disease or devil's grip, the occurrence of which in Great Britain was first described by Dr. Pickles.

Diet in Health and Disease

Edited by Sir Humphry Rolleston and Dr. Alan A. Moncrieff. (Published on behalf of the *Practitioner*.) Pp. 382. (London: Eyre and Spottiswoode, Ltd., 1939.) 14*s*. net.

MORE than thirty years have elapsed since the appearance of the last important British compendium on diet, edited by the late Dr. G. A. Sutherland, so that a new book on the subject was urgently needed. Most of the articles in the work have already been published in the *Practitioner*, but they have been revised and a few new ones have been added. The book contains twenty-eight chapters contributed by thirty-two specialists. The chapters on diet in health deal with the various forms of infant feeding, diet in childhood, old age, winter and summer, pregnancy and lactation, and in the tropics, while the chapters on diet in disease are concerned with sick-room menus and recipes, diseases of the various systems and allergic diseases. A special chapter is devoted to alcohol, the dietetic use of which has been greatly reduced in recent years. The up-to-date and practical advice in which the work abounds will render it a useful handbook to the practitioner and student.

The Handicap of Deafness

By Irene R. Ewing and Dr. Alex. W. G. Ewing. Pp. x+328+3 plates. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1938.) 12*s*. 6*d*. net.

THIS book contains a unique record of experience in a particularly arduous field of social science, and is likely indeed to fulfil the aims of its authors to provide a working source of information alike for the deaf and those who serve them. The difficulties which beset the management of the deaf are dealt with in a manner connoting wide knowledge and technical competence, and the lessons to be learned are both valuable and clearly defined. Particularly striking are the figures showing the time wasted in chronic deafness in adults before the initiation of lip reading, its importance in reinforcing any hearing aid, and the high percentage of deafened adults who can be considerably assisted by modern electrical apparatus.

The sections dealing with the measurement of deafness are eminently sound. Intelligibility of speech is very properly made the basic test, and the reviewer particularly welcomes the emphasis laid upon the necessity in such tests of excluding the influence of context. The method adopted of nonsense syllables is probably the best available, but more emphasis might have been laid upon the necessity for highly trained personnel for its successful application; and there seems little reason why this in its turn should not in due course be placed upon an electrical basis. Some lack of accord between pure tone threshold tests and intelligibility in the earlier stages of deafness is recognized and accords with the more empirical observations of clinicians. One of the best chapters is that which describes deafness and its recognition in the young child. The influence of Mr. T. S. Littler's technical contributions is apparent throughout this book and is frequently acknowledged by its authors. C. S. H.

Biography of the Unborn

By Margaret Shea Gilbert. Pp. x+132. (London: John Murray, 1939.) 5*s.* net.

THIS little book surveys in simple language the development of the human embryo during its nine months of intra-uterine life. Fertilization, the role of the sex chromosomes, the genesis of twins and the occurrence of malformations are also briefly dealt with. The descriptions are illustrated with numerous diagrams which clearly depict the changes that occur as growth proceeds from month to month.

The book gives an accurate summary of the subject, but is scarcely advanced enough or sufficiently scientific for the student or medical practitioner. For the layman who is interested in the subject, and for whom it is primarily intended, it can be recommended.

METALLURGY

Metallurgy for Engineers

By E. C. Rollason. Pp. viii+272. (London: Edward Arnold and Co., 1939.) 10*s.* net.

NO words are wasted in this book, the purchaser of which receives about seven hundred per penny, together with some 150 illustrations, including many clever diagrams which amplify the text. Here indeed is value for money which no student can readily ignore. The most serious criticism which can be made of the book is that it is too concise and may encourage 'cramming'. Although the preface indicates that the book is intended for use in conjunction with a teacher, this does not absolve the author from responsibility, and one would like to see, in the next edition, fewer statements of fact and more explanations of basic principles.

Practical Microscopical Metallography

By Dr. Richard Henry Greaves and Harold Wrighton. Third edition, revised and enlarged. Pp. xi+272+60 plates. (London: Chapman and Hall, Ltd., 1939.) 18*s.* net.

A DISTINGUISHED research metallurgist collaborated with a virtuoso of the metallographic microscope to produce, in 1924, the first edition of this book. It has become the standard work on the subject, and one turns from the second edition with a tinge of regret, to greet the new friend. The authors still refuse to call it a text-book, although it is far more than a series of annotated photomicrographs. Many of these are, as in the previous editions, superb, and most of them are excellent: one or two permit the average metallographer to regain his self-respect, at least for a moment. The descriptions of technique are even more extensive and the practical hints on low-power work are particularly welcome. Discussion of the 'austemper' process, photomicrographs of typical disintegration-proof 18-8 steels, and particulars of the electrolytic cyanide etch for precipitated carbides, might be included with advantage in the next edition.

MISCELLANY

The Growth of Science

An Outline History. By A. P. Rossiter. (Published for the Orthological Institute.) Pp. 372. (London: Sir Isaac Pitman and Sons, Ltd., 1939.) 5*s.* net.

THIS little book will prove very useful from many points of view. It gives an authoritative account of the leading stages of the history of science. Then it connects the various fields of science in a way which helps the reader to understand the unity of its development. Moreover, it gives a short explanation of the notions involved in the problems discussed. Finally, it gives a good illustration of what can be done in this field by a judicious use of Basic English. Controversial issues are wisely avoided; and as the book is short, one feels less the monotony of the basic vocabulary and syntax ably used by the author. In itself, this work is an excellent popular introduction to the history of science.

The Language of Gesture

By Dr. Macdonald Critchley. Pp. 128. (London: Edward Arnold and Co., 1939.) 5*s.* net.

AS students of human speech still concentrate primarily on its sounds rather than on the muscular movements which produce them, it is well that specialists like Dr. Macdonald Critchley should intervene. He has brought together, in 124 pages, a larger volume of valuable material than has so far been available. It is surprising, however, that though the author pays great attention to gesture language—including copious references to the scattered literature on the subject—he does not mention Darwin's observation on the sympathy of movement between man's hand and mouth, which constitutes the fundamental link between primitive descriptive gesture and the significant mouth movements of speech. Nor does he clearly define the difference between instinctive pantomime—such as that of the born deaf—which describes events as a whole, and the acquired sign languages—such as that of the Red Indians—in which each sign stands for a separate unit of thought, equivalent to a 'word'. The origin of these units of thought deserves thorough investigation.

The reference to Armenian sign language (p. 50) needs correction. The language is used exclusively by women—not by men. The descriptions of hand gestures might have been made easier; "pronated", "adducted", etc., will be unfamiliar terms to many of the wide public by whom this excellent little book should be read.

Land Drainage and Reclamation

By Prof. Quincy Claude Ayres and Prof. Daniels Scoates. (McGraw-Hill Publications in Agricultural Engineering.) Second edition. Pp. xi+496. (New York and London: McGraw-Hill Book Co. Inc., 1939.) 26*s*.

THIS work is of the nature of a text-book and as such is particularly designed for American State colleges, in that the usual problems associated with each subject are asked at the end of each chapter. Survey with levelling is taught and then the technique of drawing, the open ditch method and the use of earth dams being especially carefully explained. Land clearing by grazing, cutting and burning encourages soil erosion which has to be controlled. This leads to the consideration of the terracing of fields and the use of check dams in gullies. Finally, sub-surface draining is considered, and the use of mechanical means in the cutting of the necessary trenches for drain pipes. Where there are wide areas of similar land as in Iowa and Texas the methods recommended can be applied. In Great Britain, with its much greater variation in topography and geology, this book will only be helpful in suggesting methods, the consideration of the drainage of each farm being a little research of its own.

Begin Here

A War-Time Essay. By Dorothy L. Sayers. Pp. 160. (London: Victor Gollancz, Ltd., 1940.) 6*s*. net.

MISS DOROTHY L. SAYERS, for the moment breaking free from her pre-occupations with the writing of detective stories and the drama, has presented her numerous public with a War-time essay. Her somewhat cryptic title expresses her firm conviction that now and not the end of the War is the time for pondering and planning the post-War world in which we are to emerge from the present struggle. Her vigorous call for constructive thinking on the part of the average citizen for whom she writes is based, as befits so informed a student of the medieval world, upon an acute analysis of the main currents of thought and emotion which contributed to making Europe of the Middle Ages something of a homogeneous whole. Possibly there is a tendency in a certain group of writers on historical topics to overstress this unity. Be that as it may, Miss Sayers recognizes that the revival of learning and the growth of the spirit of inquiry made impossible a return to that unity of thought and emotion, with all its implications as a condition of peaceful relations among the people of Europe. It is the business of constructive thinking to arrive at a form of relation in modern civilization which in like manner will bring about not a static, but a dynamic, condition of peace. Miss Sayers is emphatic in pointing out that this is to be achieved not by consideration of the requirements of 'economic man' or psychological considerations but only of the whole nature of man in which the part of emotion as well as reason attains free play.

Uses of Lac

By Dr. H. K. Sen and S. Ranganathan. Pp. 79+20 plates. (Namkum: Indian Lac Research Institute, 1939.) 1.4 rupees.

THIS little book is intended primarily to interest Indian manufacturers and industrialists as potential users of lac and shellac. The authors point out that since the consumption of lac in India is only 2–3 per cent of the exported amount, there should be considerable room for expansion in that country. The book, however, should have a definite appeal to the average reader, seeking knowledge of the origin and uses of this unique natural resin. Many of the more important applications of this raw material are briefly described and there are numerous practical recipes.

Among the large amount of data given, the table (p. 15) showing the export figures for the past twenty years is of particular interest inasmuch as it demonstrates that lac is more than holding its own in face of competitive synthetic resins.

The book is attractively printed with well-defined headings and sections, and amply illustrated by numerous photographs showing the diverse uses of shellac and its commercial products. The clarity of some of the illustrations, however, appears to have suffered in reproduction.

PHILOSOPHY AND PSYCHOLOGY

The Structure of Aristotelian Logic

By Prof. James Wilkinson Miller. (Psyche Monographs, No. 11.) Pp. 97. (London: Kegan Paul and Co., Ltd., 1938.) 10*s*. 6*d*. net.

THE principal aim of this able book is to effect the reorganizations required in traditional logic by the introduction of negative terms, which occurred technically during last century; and also to give a rigorous presentation of traditional logic as containing negative terms.

The former analysis of Aristotelian logic given by the author introduces new definitions, postulates and distinctions necessitated by the symbolization of the system. This formalization makes traditional logic look much poorer than the so-called recent generalizations of the subject. It could scarcely be otherwise; for this treatment of the Aristotelian system takes, so to speak, all the blood out of it. It is not its mere formalization that gives an inferential necessity to this system; but also and mainly its ontological and qualitative background. One without the other gives an unfair picture of traditional logic, especially as the author of the book assumes without proof that the fundamental principles of Aristotelian logic are less general than those of modern mathematical logic. As it is, however, the book should help to build up a more satisfactory valuation of Aristotelian logic, provided one takes into account most of the relevant subjects which the author omits deliberately in his discussion.

Cosmology

A Text for Colleges. By Prof. J. A. McWilliams. Second revised edition. Pp. x+243. (New York: The Macmillan Company, 1938.) 9*s*. net.

To many readers this book will seem old-fashioned, with little reference to the technical problems which face the modern scientific worker. For one thing, the bibliographies given at the end of each chapter and at the end of the book show a complete disregard of the recent technical literature by leading specialists on mathematical and physical theory. Father McWilliams approaches his problems from a scholastic angle. But there is no reason for giving the impression that scholasticism is necessarily backward.

Many readers would be interested to know how the fundamental ontological and cosmological theories of scholasticism can be interpreted in terms of modern scientific discoveries; and this interpretation is, no doubt, possible. This book, however, is valuable in suggesting such an approach, provided one could go much further than the elementary details it takes into account. The argumentative method adopted is also refreshing. As to the controversial issues involved, the author repeats the classical solutions, where he could use, with greater effect, examples and arguments from recent scientific discoveries.

PHYSIOLOGY

Nahrung und Ernährung

Altbekanntes und Neuerforschtes vom Essen. Von Dr. Hans Glatzel. (Verständliche Wissenschaft, Band 39.) Pp. vii+256. (Berlin: Julius Springer, 1939.) 4.80 gold marks.

The author of this book set himself the task of presenting the elements of the science of nutrition in a manner which would make them intelligible to every German citizen. An introductory section discusses food and nutrition in the animal kingdom and the physiological basis of nutrition. Dr. Glatzel then considers the composition and distribution of the foodstuffs within the Third Reich and the effective methods of conditioning, preserving and cooking. The role of the sense-organs in digestion is adequately described and, in the treatment of the hygiene of eating, the author takes great pains to emphasize the distinction between hunger and appetite. In dealing with food-requirements and the variations, the effectiveness of the Allied blockade in 1914–18 receives considerable prominence, indications being made to suggest that such a condition can never again be possible in Germany. Particular food-fads and dietetic methods are examined and, where necessary, exposed. In an excellent chapter the author discusses the significance of food and nutrition in myth and religion. In conclusion, nutrition is related to the social problem, due regard being paid to the organization of Germany's food economy. The real purpose of the book is revealed in its last sentence: "Von den Nahrungs-wahl jedes einzelnen, von seinem gutem Willen und seiner Einsicht hängt es aber auch ab, wie schnell und wie vollständig wir das grosse Ziel erreichen: *Deutschlands Nahrungsfreiheit*."

A glossary and suggestions for further reading are appended, although there is no index. T. H. H.

The Newer Knowledge of Nutrition

By Prof. E. V. McCollum, Dr. Elsa Orent-Keiles and Dr. Harry G. Day. Fifth edition, entirely rewritten. Pp. ix+701. (New York: The Macmillan Company, 1939.) 18*s*. net.

It is like meeting an old and much-loved friend after many years to have in one's hand a new edition of "McCollum". This is the fifth and it appears after an interval of no less than ten years, which is a whole epoch in the recent history of nutritional science. In its preparation Prof. McCollum has had the assistance of two collaborators, Elsa Orent-Keiles and Harry G. Day, and I rather feel the work has to a slight extent lost individuality as a result. But that is a small fault to find with a work that so ably and so adequately reviews the wide range of human and animal nutrition. Indeed, instead of a slight sense of disappointment that the book has not quite the 'personality' earlier editions had, one should feel very grateful that Prof. McCollum and his two colleagues have succeeded in producing a little more than six hundred very readable pages from their survey of so vast a literature. It need scarcely be said that the work is indispensable to all who wish to keep abreast with nutritional science and its application to human and animal welfare. But Prof. McCollum must realize that having produced what has for long been regarded as a standard work, we shall all be greatly disappointed if we are obliged to wait ten years for the next edition. J. C. DRUMMOND.

The Physiological Basis of the Art of Singing

By Haydn Hemery. Pp. xviii+139. (London: H. K. Lewis and Co., Ltd., 1939.) 10*s*. 6*d*. net.

Singing is without question an art, but there should be at least an element of science in the training of singers. The technique employed is very difficult to discover from conversation with teachers of singing. The difficulty is partly due to lack of common vocabulary, and too often also the same words are used by singers and scientists with quite different meanings.

The literature of voice training is comparatively small. The 'secrets' of the teachers have been for the most part passed down by word of mouth from one generation to the next. Mr. Hemery has attempted to supply the written deficiencies in a way in which teachers of singing can learn more of the scientific side of their work. The simple and clear anatomical diagrams are perhaps the most valuable part of the book.

For the scientific reader the book is scarcely satisfying, nearly every page leaving a number of queries in the mind. Moreover, the science is curiously mixed with unscientific statements, as, for example, in the numbered captions to one of the chapters, which runs thus: "Love is unification at an emotional level, for it is impossible to love and be wise."

PRINTED IN GREAT BRITAIN BY FISHER, KNIGHT AND CO., LTD. ST. ALBANS

duction of flavour in bacon and ham (Food Investigation Special Report No. 49. "The Function of Nitrate, Nitrite, and Bacteria in the Curing of Bacon and Ham". H.M. Stationery Office. 9*d.* net). Curing of pork for bacon and ham was originally a process of dry salting. Now, the pickle used is liquid, and the process is supplemented by injecting the pickle into the tissues of the carcass. The traditional pickling materials—salt and saltpetre—are still used in Great Britain, but it has long been known that the 'cured colour' is due to the formation of nitrite by the action of bacteria upon the saltpetre. The nitrite formed reacts with the blood colouring matter present to form a special pigment, nitroso-hæmoglobin. It is shown that a satisfactory English bacon can be made by using only sodium chloride and sodium nitrite in the pickle, and that bacteria and nitrate are not essential for the development of the flavour. A very small content of free nitrite, as low as ten parts per million in the final product, is sufficient to produce a satisfactory flavour and colour. The report indicates the possibility of recasting the present practice so as to give the curer better control over the quality of this product.

The Stoic

The April number of the *Stoic* represents, not the "famed Athenian Porch", but Stowe School, which, starting at one of the great houses which flourished in the eighteenth century, has long since won its way to recognition on a par with older foundations. The school magazine is one of the best we have seen, including literary matter as well as the usual records of activities. Stowe is now responsible for two London clubs for boys. It produces its own films, which have dealt with several classes of animals and plant-life, while the Natural History Society, started last year, keeps a journal of work done which is well spoken of. The school evidently enjoys many things besides the normal curriculum. The illustrations make a good show and include a lively "Decorated Black-out Screen" designed by a young artist.

Earthquakes in the United States and in Italy

On Saturday and Sunday, May 18 and 19, severe earthquake shocks were experienced in the south-western United States and in Italy. In the United States eleven shocks were felt at places so far apart as 800 miles in Southern California and Arizona. The town of Imperial is reported in ruins, with five people killed and many injured. Owing to the disruption of communications, further details are not yet available. The place most affected in Italy appears to have been San Servo.

Other Recent Earthquakes

Reports from the seismological observatories at Kew (England) and De Bilt (Holland) confirm that there were two large earthquakes on May 4 and one on May 5. At Kew the first commenced recording at 7h. 35m. 55s. G.M.T. on May 4, and the epicentre was estimated to be distant 8,500 km. The second was received at Kew at 21h. 10m. 7s. G.M.T. on the same day, with an estimated epicentral distance of 4,770 km., and gave rise to ground amplitudes of 54 μ. The third commenced recording at 2h. 16m. 40s. G.M.T. on May 5 at Kew, and the estimated epicentral distance was 9,750 km. These readings have been confirmed by equivalent readings from De Bilt. Dr. G. van Dyk is of the opinion that the first on May 4 originated near the Aleutian Islands. which has recently been observed to be seismically active (Nature, May 4, p. 701 and earlier issues) and that the second on May 4 may have come from an easterly azimuth.

The Night Sky in June

The nights around the summer solstice on June 21 are shorter than 7½ hours in the latitude of London, reckoned from sunset to sunrise; excluding twilight (nautical) darkness lasts only about three hours. The moon is new on June 6 and full on June 19. Venus, which is still a brilliant evening star at the beginning of the month, draws rapidly towards the sun's place and is at inferior conjunction on June 26. Mercury is also an evening star in conjunction with Venus on June 12 and with Mars on June 17; on June 24 Mercury is at greatest elongation (25° east). Mars is getting less easy to see; it is close to Venus on June 7. Jupiter and Saturn are both morning stars, the former rising soon after 1h. 30m. U.T. on June 16, followed ¼ hr. later by Saturn. At dusk in mid-June, the red star Antares is about south. Arcturus has already southed, while Vega is some 3 hours before the meridian. The constellations, Boötes, Hercules and Ophiuchus contain some interesting double stars of which ε Boötis (2·8″), ξ Bootis (5·1″), α Herculis (4·8″) and 70 Ophiuchi (6·6″) are good examples. Between η and ζ Herculis may be glimpsed with the naked eye under favourable conditions the great star cluster, *M*13, the distance of which is of the order 35,000 light years. The outer part of the cluster can be resolved into stars with a 2½- or 3-inch refractor. The Scorpiid meteors are at their greatest frequency about June 4, their radiant point being north, following Antares.

Announcements

The Editors of Nature have decided that, for the time being, the receipt of the manuscript of contributions cannot be acknowledged. Furthermore, it is found essential to reduce the number of proofs sent to the author of contributions submitted to one. This proof must be accepted as an acknowledgement of receipt of the copy.

Among his personal assistants, the Prime Minister has appointed Prof. F. A. Lindemann, F.R.S., professor of experimental philosophy in the University of Oxford, for advice concerning statistics and research.

Dr. H. Shaw, keeper in the Department of Physics and Geophysics at the Science Museum, has been appointed acting director of the Museum during the absence of Brigadier E. E. B. Mackintosh.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 825. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

Transformation of Mesotrons into Electrons

EVIDENCE for the transformation of mesotrons into electrons was recently reported in these columns[1]. This was obtained by the use of the cloud chamber, and consisted in the observation of a fast electron track emanating from the end of the track of a mesotron. What appears to be another instance of this phenomenon was recently observed in this laboratory, though on account of the tracks being rather old and accompanied by other old tracks the photograph is not as good as the earlier one. Apart from a further indication of the frequency of occurrence of the phenomenon, it does not give any new information.

The probability of catching a mesotron coming to the end of its range in a cloud chamber, with random expansions, is greatly enhanced if the chamber is large or contains gas at a high pressure. In the work previously reported a large chamber (60 cm. diameter, 50 cm. deep) operating at atmospheric pressure was used. (This chamber has since been operated at four atmospheres.) The present tracks were observed in a cloud chamber of moderate dimensions (20 cm. diameter, 16 cm. deep) containing argon at 80 atmospheres. A distance of 15 cm. in this chamber is equivalent in stopping-power to about 2 cm. of water, or 16 metres of standard air. Actually the total length of track (old and new) of cosmic-ray particles observed up to date in the high-pressure chamber, and in the large chamber, is equivalent to about 5×10^6 cm. of standard air. The observation in these experiments of two mesotron-ends thus corresponds to 4×10^{-7} mesotron-ends per cm. of cosmic-ray track in air. The number expected as the result of the slowing down of fast mesotrons (cf. ref. 3, p. 210) is equal to the product of the number of fast mesotrons (energy $T, \sim 5 \times 10^8$ volts) per unit energy interval per cosmic-ray particle, the rate of loss of energy in air by fast mesotrons (energy T), and the decay factor for mesotrons of energy T under the conditions concerned, $\sim 3 \times 10^{-4}$ per Mev. $\times 3 \times 10^{-3}$ Mev. per cm. $\times 0{\cdot}6 \sim 5 \times 10^{-7}$ per cm. The rough agreement with the observed frequency, and a similar agreement regarding the number of slow mesotrons observed in earlier work[2,3] indicate that there is not a very high probability for the removal of a mesotron from the cosmic-ray beam by some hitherto unknown process, unless there is a creation of slow mesotrons which happens to compensate roughly for the removal of fast ones.

The photograph referred to above is reproduced in Fig. 1. AB and BC represent the tracks concerned. The appearance of these is consistent with a mesotron AB coming to the end of its range at B and transforming into an electron BC. The tracks in the neighbourhood of B show that the illumination was fairly uniform in that region. That AB is the track of a slow particle ($v \ll c$) is shown by the relative high density of ionization along it as compared with BC. It might be pointed out that the length of dense track rules out an electron as the responsible particle, since at these pressures an electron is fast up to the last few millimetres of its range. (It will be noticed that a track which enters the chamber near A appears also to terminate in the gas with a faint track leaving the neighbourhood of its end. While this resembles a mesotron disintegration more than anything seen in all the other photographs (about 1,400) the conditions near the end of the track, such as weak illumination, are too poor to warrant any inferences. It may possibly be the track of opposite sign to AB, separated from it by the electric field.)

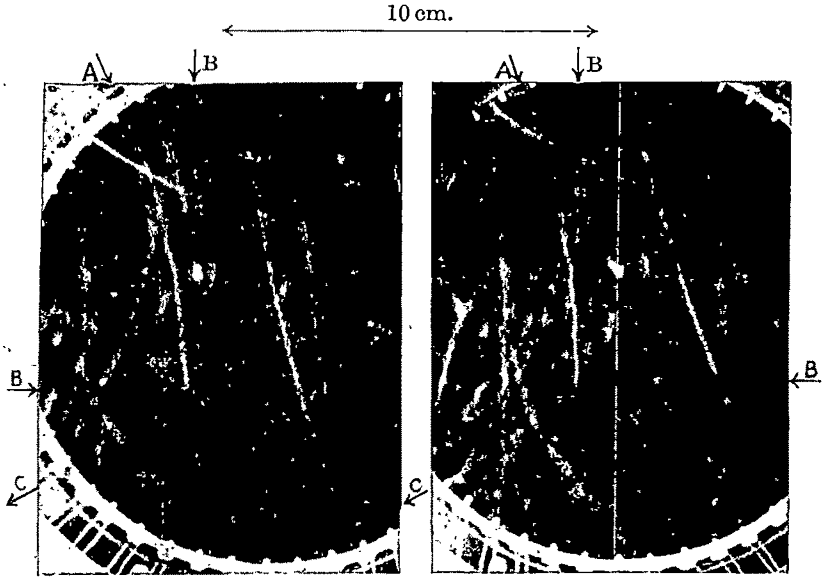

Fig. 1.

FOR STEREOSCOPIC VISION, THE LEFT-HAND PHOTOGRAPH SHOULD BE VIEWED BY THE RIGHT EYE, AND *vice versa*.

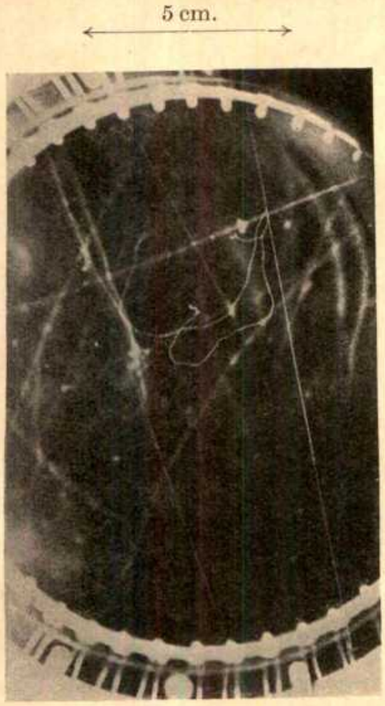

Fig. 2.

It is of interest to consider the probability of the occurrence of the tracks *AB*, *BC* by the chance coincidence of the beginning of a fast high-energy track with the end of a heavy track. In all the other photographs taken with the high-pressure chamber, about 1,200, there is only one clear case of a heavy track—probably a proton—terminating in the chamber, and about half a dozen doubtful cases of tracks, not necessarily heavy, ending or beginning in the chamber. Even assuming that one fast track starts in the chamber in every photograph, which is a gross over-estimate, the above probability is then of the order of 6 × (thickness of track)^3 ÷ (volume of illuminated part of chamber) $\sim 6 \times (0{\cdot}1 \text{ cm.})^3 \div (13^2 \text{ cm.}^2 \times 5 \text{ cm.}) \sim 10^{-5}$. The corresponding upper limit to the probability of the chance imitation of the example observed in the large chamber reported earlier[1], is $1 \times (0{\cdot}04 \text{ cm.})^3 \div (40^2 \text{ cm.}^2 \times 12 \text{ cm.}) \sim 10^{-8}$. The probability of both examples being an accidental coincidence is accordingly much less than 10^{-13}.

AB is obviously distorted by scattering, while both *AB* and *BC* are probably distorted by air-motion and by the electric field (before condensation). Their radius of curvature ($\sim$ 25 cm. for each) has therefore no significance of value. It might, however, be mentioned that a mesotron of the same range, with a mass one tenth that of a proton, would have an overall radius of curvature of about 50 cm. due to the magnetic field (2,700 gauss) and a natural curvature, due to scattering, equal on the average to about 30 cm. (For a proton these would be greater by factors of about 5 and 3 respectively.) If the electron, *BC*, had half the mass energy of the mesotron ($\sim$ 40 Mev.), its radius of curvature due to the field would be about 50 cm., and about 350 cm. due to scattering.

We reproduce in Fig. 2 a photograph, taken under the same conditions as that reproduced in Fig. 1, showing two sharp tracks, which is about the average number of sharp tracks per photograph. These are little disturbed by air motion. One is seen to produce two fast secondary electrons, the angles of projection of which indicate an initial energy of about 3 Mev., corresponding to a range of about 15 metres of air at N.T.P.

Classical Theory of Point Dipoles

It is well known that a limit to the validity of quantum mechanics is set by its neglect of the effects of radiation damping, and an indication as to where this limit occurs is given in electron theory by the classical equation of Lorentz, which takes radiation damping into account. Now the interaction of the meson field with a neutron or proton contains an explicit dipole term, and this leads to scattering cross-sections for mesons which increase quadratically with the energy. A classical treatment of radiation damping for a dipole would thus give us the limits of the quantum theory due to neglect of this factor. A non-relativistic attempt has already been made by Heisenberg[1] for a dipole of finite extension, but his results even in the limit of a point dipole do not agree with ours. We believe that this is because the usual method of calculation which he follows is inconsistent with the theory of relativity, for whereas the retardation of the field is taken into account, different parts of the dipole are assumed to move instantaneously in phase.

The method used by Dirac[2] for a point electron, and by me[3] in the classical theory of mesons, has been extended for finding the exact classical relativistic equations for the motion of a point-dipole described by a six-vector $S_{\mu\nu}$.

It will be shown in a paper with Corben that the flow of energy and momentum out of a world-tube of radius ε surrounding the world-line of the dipole contains certain terms which tend to infinity as $\varepsilon \to 0$, but these are all perfect differentials, and hence may be subtracted as in the previous papers. The flow of ***total*** angular momentum out of the tube (including the *orbital angular momentum*)[4] contains similar singular terms, but these are also perfect differentials and may be subtracted as before (the calculation of the singular terms is entirely due to Dr. H. C. Corben). Thus completely definite equations free from singularities can be found for the rotation and translation of a point dipole.

Using these results, I have been able to show the following:

The charge g_1 and dipole moment g_2 are independent constants, and the mass M and angular momentum of the spin I also appear as *independent* and arbitrary constants in the equations. Further, it is also true in the special case $S_{\mu\nu} v^\nu = 0$ (v^ν is the 4-velocity of the dipole), where the dipole is always a pure magnetic dipole in the system in which it has no translational motion. This is in definite disagreement with a paper by Kramers[5] in which a relation between the four constants was deduced.

The case where $S_{\mu\nu}v^{\nu}$ is variable can be treated quite consistently, and *if* radiation damping be neglected, is mathematically simpler than the case $S_{\mu\nu}v^{\nu} = 0$. But when radiation damping is taken into account, the former is vastly more complicated than the latter. It is satisfactory to find that it is the simpler case which is the only one to occur in Nature. The complete rotational and translational equations when $S_{\mu\nu}v^{\nu} = 0$ have already been given elsewhere[6] for the special case $g_1 = 0$, $g_2 \neq 0$.

In view of what has been said above, if we wish to consider only the rotational motion of the dipole, we may let the mass M of the dipole tend to infinity, in which case v_{μ} and its derivatives vanish. The rotational equations then take on a particularly simple form, namely

$$I \dot{S}_{kl} = g_2(S_{km} F^m{}_l - S_{lm} F^m{}_k) - \frac{2}{3} g_2{}^2 (S_{km} \dddot{S}^m{}_l - S_{lm} \dddot{S}^m{}_k) \quad . \quad (1)$$

Here $F_{\mu\nu}$ is the ingoing electromagnetic field. The last term gives the effect of radiation damping.

With these equations, the cross-section for the scattering of light of frequency $\omega/2\pi$ by the dipole is[6]

$$6\pi \frac{\omega^2 \sin^2 \theta}{\omega^4 + 9I^2/4g_2{}^4}, \quad . \quad . \quad . \quad . \quad . \quad (2)$$

where θ is the angle between the magnetic force of the light wave and the axis of the magnetic dipole. For small ω this becomes

$$\frac{8\pi}{3} \frac{g_2{}^4}{I^2} \omega^2 \sin^2 \theta, \quad . \quad . \quad . \quad . \quad . \quad (3)$$

which is the cross-section previously calculated on the quantum theory. It *increases* as ω^2. For large ω, however, the exact cross-section (1) becomes

$$6\pi \frac{\sin^2 \theta}{\omega^2},$$

and thus *decreases* as ω^{-2}.

Although (2) is strictly valid only for the scattering of light, it may be used to give an estimate of the scattering of meson waves by neutrons, for, as has been shown in a previous paper[3], the existence of the finite rest mass μ of the meson only *decreases* the above cross-section for energies $\hbar\omega \sim \mu$, while the cross-section is not appreciably altered for $\hbar\omega \gg \mu$.

The equation (1) and the cross-section (2) show that radiation damping becomes important when

$$\hbar\omega \gtrsim \hbar \sqrt{\frac{3I}{2g_2{}^2}}.$$

Putting $I = \hbar/2$ for a neutron, and the empirical value $g_2 = g_1\hbar/\mu$ (μ = meson mass) for the meson field, this gives

$$\hbar\omega \gtrsim \mu \sqrt{\frac{3\hbar}{2g_1{}^2}} \sim 2\mu.$$

(The velocity of light has been put equal to unity.) Thus we should expect the quantum theory of the meson neutron interaction to fail for energies higher than 2μ, *but this limit has really nothing to do with the mass of the meson and merely depends on the empirical magnitude of the constants g_2 and I.*

It is interesting to note that, whereas for the scattering of neutral mesons by neutrons quantum effects do not set in until $\hbar\omega \gtrsim M$ (where M is the neutron mass), the quantum theory already goes wrong for energies $\hbar\omega \gtrsim 2\mu$ due to neglect of radiation damping. Thus, contrary to what happens in electron theory, there is a region of energy $2\mu < \hbar\omega < M$ where the classical formula (2) will be correct, but the quantum formula (3) quite wrong.

To apply the same formula to the spin of the *meson* and its interaction with *electromagnetic fields*, we put $I = \hbar$, $g_2 = e\hbar/2\mu$, and find that the quantum theory of this interaction should fail when

$$\hbar\omega \gtrsim \mu \sqrt{\frac{6\hbar}{e^2}} \sim 28\,\mu,$$

a limit which is much higher than the limit given above at which the theory of nuclear interaction fails.

An electron has no explicit g_2 spin interaction with the Maxwell field, but *if* the above theory is applicable to its spin, then putting $I = \hbar/2$, $g_2 = e\hbar/2m$, we should expect the quantum theory of the electron to fail for energies

$$\hbar\omega \gtrsim m \sqrt{\frac{3\hbar}{e^2}} \sim \sqrt{(3 \times 137)}\, m,$$

that is, at energies much lower than 137 m, which has been hitherto supposed.

Thus our theory shows that a proper consideration of radiation damping automatically cuts down the scattering due to the spin term, and hence there is no necessity whatever for the *ad hoc* introduction of higher spin states as has been done by Heitler[7] in a recent note. In a previous paper[3] it was shown that the finite mass of the meson does not lead to Heisenberg explosions, and our present calculations show that the g_2 spin interaction does not give rise to these either.

The general theory will be published elsewhere with H. C. Corben when circumstances permit. Difficulties of communication have prevented a joint publication in the present instance.

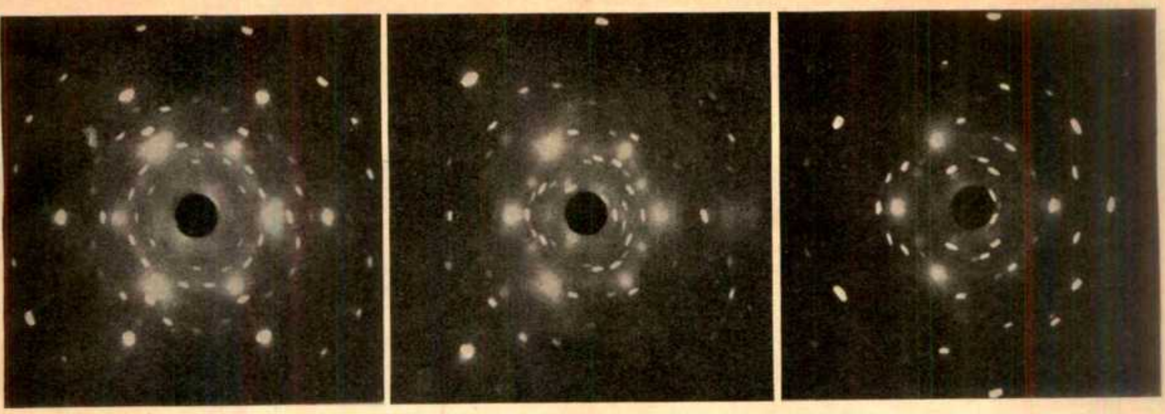
Anomalous X-Ray Reflections on Laue Photographs

Sir C. V. Raman and P. Nilakantan[1] have described a type of specular X-ray reflection to be found on Laue photographs of diamond taken with copper radiation normal to a (111) plane.

We wish to point out that similar effects have previously been observed by several workers[2]. In some of these cases the anomalies are due to mechanical strain or to age-hardening, but these explanations do not appear to account for all the observed phenomena, and a more general theory has been offered by G. D. Preston[3] in terms of the thermal vibrations of groups of atoms. His photographs of aluminium, sodium chloride and magnesium oxide show, in addition to the usual Laue diagram, a pattern of more diffuse spots which are greatly enhanced at high temperatures and remain even when the radiation is strictly monochromatized and the Laue pattern has disappeared.



a X-RAYS ALONG [0001] AXIS. *b* X-RAYS 10° FROM [0001] AXIS. *c* X-RAYS 15° FROM [0001] AXIS.

BENZIL; UNFILTERED COPPER RADIATION; 70 MIN. EXPOSURE AT 3·5 CM.

Many Laue photographs obtained in this laboratory over a period of years, using diamond, sodium, rock-salt and other compounds, show the effect; perhaps some of the most beautiful are those of benzil, here reproduced. It is significant that these anomalous patterns are much less sensitive to crystal mis-setting than are the ordinary Laue diagrams. In our opinion, further experimental evidence is desirable before any theory can be accepted as essentially correct.

Optics of the Artificial Nylon Fibre

THE fibrils of which the artificial 'Nylon' fibre is composed exhibit a remarkably high double refraction. Although their diameter is only about 19 μ, they show interference colours of the third order. For the calculation of the double refraction their slightly elliptical cross-section must be taken into consideration. The large and the small diameter can easily be measured under the microscope with slightly twisted fibrils. The double refraction of the fibrils examined amounts to 0·060, the lower index n_a being 1·520 and the higher index n_γ about 1·580. It is surprising how closely these figures agree with those of silk fibroin[1] and natural cellulose fibres[2] (see table). When the fibrils are stretched they prove to be strikingly photo-elastic; the retardation may increase by 30 per cent before the fibril breaks.

	'Nylon'	Silk	Ramie
$(n_\gamma)D$	1·580	1·584	1·599
$(n_a)D$	1·520	1·529	1·532
Double refraction	0·060	0·057	0·067

Oxide Films on Alloy Steels

IN a recent communication[1], T. Tokumitu concludes that the naturally occurring oxide film on stainless steels is α-$(Fe,Cr)_2O_3$, and he bases this conclusion upon the fact that heating the natural oxide layer to 600° C. for one hour suffices to change the electron diffraction pattern from one of blurred rings which cannot be analysed, to a well-defined pattern of α-$(Fe,Cr)_2O_3$. The crystalline structure adopted by the film on heating, however, may very well be different from that of the natural oxide, and even the chemical composition may be changed, since, unless the heating is carried out in an exceedingly good vacuum or its equivalent, the film may gain oxygen, and also, as Pfeil[2] has shown in the case of thick scales, diffusion of metal atoms towards the oxide surface occurs at high temperatures.

Furthermore, the work of Jackson and Quarrell[3] shows that when the electron diffraction examination of oxide films is carried out at room temperature, the results are apt to be misleading. Thus, with 'Armco' iron and plain carbon steel specimens, oxide films formed and examined at temperatures of 350°, 600° and 950° C. gave patterns corresponding to Fe_3O_4, FeO and Fe_3O_4 respectively, but on examination at room temperature all three surfaces gave the pattern which is generally attributed to Fe_3O_4. Indeed, it was possible to correlate the oxide structure with the temperature of formation by using the new high-temperature technique and to show, for example, that, on cooling, the Fe_3O_4 formed above the A_3 critical point of the metal specimen passed through two transformations corresponding to $Fe_3O_4 \rightarrow FeO \rightarrow Fe_3O_4$. In view of the possibility of such changes occurring in other cases, it is not advisable to attach too great an importance to the electron diffraction patterns of oxide films recorded at room temperature.

Recent application of the high-temperature method of electron diffraction to thin oxide films formed on a heat-resisting steel of the composition 0·47 per cent carbon, 0·72 per cent manganese, 1·7 per cent silicon, 12·9 per cent nickel, 13·1 per cent chromium and 3·1 per cent molybdenum, has shown that at temperatures up to 950° C. the oxide has a spinel structure. The spinel structure is possessed by a large number of oxides of the general type $XO.Y_2O_3$, and minerals are obtained in which the X positions on the lattice are shared among two or more metals, and there is also evidence that the X and Y atoms are interchangeable. Only small differences in lattice parameters are observed among the oxide spinels, and it seems, therefore, that the spinel structure is both exceedingly flexible and inherently stable. The relative instability of the $FeO.Fe_2O_3$ spinel on 'Armco' iron must be regarded as exceptional and attributable to the fact that both X and Y lattice positions are occupied by atoms of the same metal, thus making possible the $Fe_3O_4 \rightarrow FeO$ transformation. With the more general type of spinel oxide, containing at least two different metals, a corresponding change is not possible, and therefore the structure should be stable over a much wider range of temperatures. The oxide formed on nickel-chromium alloys has been shown to have a spinel structure and probably a composition corresponding to $NiO.Cr_2O_3$. There can be no doubt that in this case the spinel affords excellent protection against further oxidation at high temperatures.

In view of the foregoing, it seems reasonable to suggest that the oxidation resistance of heat-resisting steels is largely due to the formation of a stable spinel. Provided such elements as nickel, chromium and aluminium are present in sufficient quantities, the spinel structure should be stabilized and should, moreover, be able to accommodate almost any metal which may be added to the steel for the purpose of improving its mechanical properties at high temperatures. The absence of lattice changes on heating and cooling will prevent easy access of oxygen to the underlying metal surface and so greatly increase the oxidation resistance.

Benzanthrones

In a previous publication[1] it was stated that, contrary to Schaarschmidt and Georgeacopol[2], the ring closure of *o*-α-naphthylbenzoic acid gave a mixture of *meso*benzanthrone and 3 : 4-benzfluorenone.

Since then, Grieve and Hey[3] have reported the same results as Schaarschmidt and Georgeacopol[2], without the isolation of 3 : 4-benzfluorenone. I had to repeat my experiments later, using different condensing agents (concentrated sulphuric acid, phosphorus pentachloride followed by aluminium chloride, and phosphorus pentoxide) at different temperatures. In none of these attempts, however, was *meso*benzanthrone obtained free from 3 : 4-benzfluorenone.

The condensation of diazotized methyl anthranilate with α- and β-methylnaphthalene[4] at 25° gave, in a poor yield, a mixture of acids and *o*-2′-methyl-1′-naphthylbenzoic acid respectively. The yield was improved by altering the condition of the reaction.

o-4′-Methyl-1′-naphthylbenzoic acid was easily prepared by condensing 4-iodo-1-methylnaphthalene with *o*-iodobenzoic ester (cf. Baddar and Warren[1]). Cyclization of this acid gave also a mixture of 1′-methyl*meso*benzanthrone and 2-methyl-3 : 4-benzfluorenone.

Action of Ions on Acetylcholinesterase

REFERRING to the publication of D. Nachmansohn[1], we wish to direct attention to the fact that we have previously described[2] the effect of different divalent ions on the activity of acetylcholinesterase. We think that for some reason this paper did not reach Dr. Nachmansohn.

We have shown that manganese, magnesium and calcium ions are especially active ; strontium and barium ions are active to a less degree. Inhibition experiments with sodium fluoride, sodium oxalate and others and the optimal concentration of $Ca^{++}(M/500)$ for reactivation after dialysis, revealed the outstanding position of calcium as an activator of acetylcholinesterase in horse serum. We agree with the fact that the electric organ of Torpedo is a far better enzyme material ; but horse serum allowed us to demonstrate essentially the same facts as those observed by Nachmansohn, concerning the effect of divalent ions on the activity of acetylcholinesterase.

(BY CABLE.)

D. NACHMANSOHN claims[1] that his findings concerning the activation of cholinesterase by electrolytes are "in contrast" to our results reported some time ago[2]. This statement is misleading, as his results were obtained under different conditions and therefore cannot be compared with ours.

The enzyme preparation from the electric organ of Torpedo used in Nachmansohn's experiments appears to have properties unlike those of our preparation obtained from horse serum. While both preparations will hydrolyse the same substrate, there are indications that we are dealing with different enzyme complexes. For example, the activity of the serum preparation is only slightly diminished by dialysis while Nachmansohn's preparation is almost completely inactivated ; further, the serum enzyme, in contrast to Nachmansohn's preparation, may be treated with ammonium sulphate as well as evaporated to dryness without any loss of activity.

It is difficult to understand what Nachmansohn means when he says: ". . . the enzyme preparations . . . obtained from horse serum . . . appear to have been less active and of a lower degree of purity than those previously described" (by Nachmansohn), as 1 mgm. of both enzyme preparations hydrolyses 100 mgm. of acetylcholine per hour.

As pointed out in our communication, the effect of added electrolytes depends greatly on the concentration of the substrate, being much more pronounced at a lower concentration of acetylcholine (0·025 per cent). We are unable to find any evidence that Nachmansohn has carried out experiments under such conditions.

Without knowledge of our work, L. Massart and R. Dufait[3] in July 1939 reported that they had found an augmentation of cholinesterase activity by 0·002 mol. calcium which could be abolished by addition of oxalate. Though they found magnesium and manganese to act in a similar way they expressed the opinion that "calcium est l'activateur physiologique de la choline esterase du serum". As these authors used dialysed horse serum without any further purification in their experiments, it would appear that the degree of purity of the enzyme does not affect the results. We have recently repeated our experiments with a preparation of much higher purity (1 mgm. hydrolysing 200 mgm. of acetylcholine per hour) and have found it to act in exactly the same manner as previously reported by us.

It is suggested that the activation which Nachmansohn found with concentrations of potassium and sodium as high as 0·1 mol. is due to traces of bivalent ions. According to Nachmansohn's own experiments, these ions, if only present as impurities of the order of 0·01 per cent, would at least partly reactivate his enzyme preparation.

Connexion between Carbohydrate and Potassium Metabolism in the Yeast Cell

WILLSTÄTTER and co-workers[1] have shown that if glucose is added to a suspension of yeast cells, it disappears from solution and is built up into a polysaccharide (glycogen), inside the yeast cells. Only after this (in about ten minutes time) does the fermentation begin, as tested by the production of carbon dioxide.

Since it was found[2] that there are intimate connexions between carbohydrate and potassium metabolism in animals, and since it is well known that the carbohydrate metabolism of the yeast cells is in many ways similar to that of muscle, we tried whether potassium plays any part in the fermentation of sugar by the yeast cell.

The following experiments were made with a 20 per cent yeast suspension, and the figures given in the accompanying table are the amounts of sugar and potassium in 5 c.c. of centrifuged fluid. As can be seen from the table (and as has been repeatedly found in many more experiments), the glucose disappears to the extent of about 90 per cent in ten minutes and almost completely in twenty minutes. The fermentation, as tested by the production of carbon dioxide, begins in six minutes, and the amount of carbon dioxide produced is given between the tenth and fifteenth minutes. These figures serve to give some indication of the intensity of the fermentation.

CHANGES OF POTASSIUM AND GLUCOSE IN A 20 PER CENT SUSPENSION OF YEAST

(Glucose added at 0 min. All values are mgm. in 5 c.c. centrifuged fluid.

Time (minutes)	With glucose		Same with $M/2000$ iodoacetic acid		Same with $M/300$ NaF	
	K	Glucose	K	Glucose	K	Glucose
0	0·672	33·0	0·686	31·5	0·677	33·1
10	0·196	3·75	0·852	26·2	0·625	29·3
20	0·288	1·5	0·953	18·1	0·562	20·0
40	0·352	—	1·087	10·8	0·495	11·3
60	0·571	—	1·317	8·7	0·855	1·7
120	0·828	—	1·773	6·2	1·505	—
CO_2 production starts	6 min.		8 min.		8 min.	
Quantity between 10–15 min.	16·2 c.c.		1·1 c.c.		1·35 c.c.	

Of special interest is the behaviour of the potassium, which is found to decrease rapidly in the fluid during the first ten minutes while sugar is being taken into the yeast cells. When the fermentation of sugar in the cells starts, the potassium is liberated again and reaches even higher levels than before in the outer fluid.

This experiment can be repeated several times with the same yeast suspension if glucose is repeatedly added when the preceding dose of sugar has been totally fermented. In every case potassium decreases in the fluid during the up-take of glucose and increases when the production of carbon dioxide begins.

Control experiments showed that when no glucose is added to the fluid, the potassium remains constant. It is unaltered by changes in hydrogen ion concentration, and since the concentration of sodium in the fluid remains constant during glucose up-take and fermentation, the behaviour of potassium appears to be specific and not due to general permeability changes.

The action of iodoacetic acid on these processes was studied in different concentrations. $M/2000$, as the table shows, retards markedly the up-take of glucose into the cells (that is, the polysaccharide formation) so that this is incomplete even after a hundred and twenty minutes.

The small quantities of glucose which are taken up are, however, fermented, the fermentation commencing after eight minutes, but only 1·1 c.c. of carbon dioxide was produced between the tenth and fifteenth minutes.

The behaviour of potassium after iodoacetic acid is most striking. No disappearance of potassium from the fluid is seen. There is only a slight increase in potassium when the fermentation of glucose in the cells begins. Thus iodoacetic acid has inhibited both the up-take of glucose by the yeast cells and simultaneously the up-take of potassium. The inhibition of fermentation in the cells appears to be only secondary.

Phlorrhizin has no effect in concentrations as high as $M/750$, and sodium cyanide has an action only at $M/300$, when it distinctly retards all processes, though to a lesser extent than iodoacetic acid. Sodium fluoride at $M/300$ behaved similarly.

It may be noted that baker's yeast contains about 4 mgm. of potassium per gm., of which about 15 per cent can be washed out, while the rest is retained. All experiments were made with yeast which, after washing for several hours, was in equilibrium with suspension fluid as regards potassium.

The experiments show that potassium is taken up by the yeast cells simultaneously with the glycogen formation, and that with the breakdown of glycogen it is again liberated. It is a probable assumption that this movement of potassium is connected with the production of phosphoric esters of the sugars as intermediate reactions in the polymerization and breakdown of glycogen. This would agree with our findings on the role of potassium in carbohydrate metabolism in animals[2].

A detailed report will be published later.

Seed Disinfection

CERTAIN proprietary seed disinfectants and protectives which contain organo-mercury compounds as their fungicidal basis are now used extensively for disinfecting cereal seed prior to sowing. When correctly used they give an excellent control of many seed-borne diseases, but in some circumstances, injury to the grain may result, and it is the purpose of this note to indicate those conditions which may lead to such injury. These materials are also used for treating such seeds as peas, sugar-beet, etc., but the observations given here are confined to cereals.

In these seed disinfectants, the fungicidal salt is often a member of the series R. Hg. X, where R is a hydrocarbon and X an acidic radicle. In some cases mixtures of such salts are used. In this series there is a close relationship between composition and fungicidal power, the toxicity decreasing with the increase of the molecule of R. In certain circumstances such salts may produce a characteristic phytocidal effect when they are applied to, and held by, the grain in over-doses. The seed may be killed outright or it may commence to germinate and the coleoptile to appear, but further development is abnormal, characterized by thickening of the tissues of the coleoptile and stunting of the roots. Porter[1] reports that such seedlings have thickened leaf primordia with irregular crenations and lobes. Cell division is inhibited, the existing cells becoming enlarged and multinucleate, either with small nuclei or with large 'giant nuclei' which are polyploid.

We have observed that the primary roots are usually short and thickened, their development being arrested soon after they emerge. Root hairs are frequently absent, and in these cases the seminal roots are usually discoloured brown.

Typically abnormal seedlings seldom develop further, and neither they nor the killed seeds decay rapidly in the soil. We have noted this characteristic injury both in laboratory tests and in the field and we have investigated those conditions under which it may be induced. The effect of these dust disinfectants upon seed which has been treated and then stored under varying conditions has also been examined.

We have found that provided the grain shows relatively high initial germination, is of sound physical condition and is superficially dry when dusted with these materials, then no immediate injury to the grain is likely to result. If such seed has to be stored, then provided it is kept under dry, cool conditions, with adequate ventilation, it is unlikely that any significant loss of germination capacity will ensue during several months. With such well-conditioned seed it is not possible to give any markedly excessive doses, as the dust cannot be retained by superficially dry seed beyond a certain limit.

A factor of some importance appears to be the relative superficial moisture of the seed. If such seed is dusted, even at the recommended rate, that part of the bulk of seed upon which the dressing falls will retain excessive quantities. The subsequent mixing will result in a distribution throughout the bulk of a proportion of heavily over-dusted seeds. These may be killed or may produce abnormal seedlings, thus resulting in an uneven stand. Intentional or accidental application of dust to damp seed, at rates higher than those recommended, will tend to produce more markedly adverse results.

Injury may also result if dry and well-conditioned grain is treated at normal rates but is afterwards stored under damp conditions with poor ventilation.

The moisture content of the seed (as opposed to superficial moisture) is another factor we have investigated, but we have obtained little or no evidence that treated seed of a moisture content slightly above normal suffers any immediate and serious phytocidal effects. Preliminary observations suggest that seed of high moisture content which has been dusted at normal rates and then stored suffers loss of viability to no greater degree than does undusted seed of similar moisture content.

Origin of the Frow Remedy for Acarine Disease of Honey Bees

IN 1927, Mr. R. W. Frow, of Wickenby, Lincolnshire, introduced the use of the remedy (since known by his name) as a cure for acarine disease. Mr. Frow informs one of us (A. D. B.) that he has no record of the origin of the formula, but believes that he read of it in a newspaper as a means of combating free-living acari.

We are anxious to trace the origin of the formula, which is:

Nitrobenzene . .	2 parts (by measure)
Safrol oil . . .	1 part
Petrol (preferably 'Summer Shell') .	2 parts

A Colour Reaction of Diethylstilbœstrol (4.4′ dihydroxy-α, β-diethylstilbene)

Dodds *et al.*[1] discovered a series of non-steroid œstrogenic compounds, 4.4′-dihydroxy-α, β-diethylstilbene, or diethylstilbœstrol, being the most potent representative of this series. In addition to its œstrogenic effect, this compound has other effects in common with the steroid type of œstrogens; for example, it opens the vagina of infantile rats and mice, it stimulates the evolution of the uterus and prevents the appearance of 'castrate'-cells in the ventral pituitary.

Besides these effects, others have been found, for which the natural and artificial œstrogens are no longer interchangeable.

Mühlbock[2] reported on the inhibition of comb growth by the simultaneous administration of male substances with œstrogens. The natural œstrogens act in this way when administered subcutaneously or by inunction; diethylstilbœstrol, however, is active only when administered subcutaneously.

Loeser[3] claims that diethylstilbœstrol, in contradistinction to natural œstrogens, has no influence on the thyroid after intrauterine application. Levie[4] and Gaarenstroom and Levie[5] found that stilbœstrol hastens the involution of epiphyseal cartilage more than œstrone. Duyvené de Wit[6] observed no lengthening of the ovipositor of *Rhodeus amarus* by stilbœstrol.

These effects may be suitable for discriminating biologically between a solution of natural from one of artificial œstrogens, but are unlikely to provide reliable quantitative information on mixtures of the two substances. The exact estimation of small quantities of diethylstilbœstrol in solutions of œstrone or œstradiol has now been achieved, however, by means of a colour reaction.

Addition of a few drops of a 50 per cent solution of antimony pentachloride to a solution of a few micrograms of stilbœstrol in chloroform produces a fuchsin-red colour, while in more concentrated solutions a bordeaux-red precipitate is obtained. By warming the mixture the reaction becomes more sensitive; 1 γ of stilbœstrol per c.c. of chloroform can still be detected, which amounts to a dilution of 10^{-6}. The colour attains its maximum intensity after 15 min. and remains constant for another 10–15 min.

For the detection of stilbœstrol in an oily solution of natural œstrogens the fatty and unsaponifiable substances must be removed prior to the colorimetric assay, because these substances would produce a dark brown discoloration. At a thousand times higher concentration, namely, 1 mgm./c.c., natural œstrogenic substances (steroids) produce a yellow-brown coloration with antimony pentachloride. The removal of these steroids from the solution will be described elsewhere.

It is important to use alcohol-free chloroform as a solvent, since in the presence of alcohol the red colour rapidly changes to blue-violet. For the colorimetric estimation a standard diethylstilbœstrol solution of similar strength to the unknown is used. The colorimetric assay has been successfully applied to the estimation of diethylstilbœstrol in the urine and the liver of dogs after subcutaneous injection of the hormone. The amounts found colorimetrically were the same as those ascertained by biological assay. The urine extracts were purified before carrying out the assay.

Points from Foregoing Letters

E. J. Williams and G. R. Evans submit photographs providing further evidence for the transformation of mesotrons into electrons, the first evidence for which was obtained at the same laboratory a short time ago. The experiments were carried out in a high-pressure cloud chamber containing argon at a pressure of 80 atmospheres.

H. J. Bhabha has extended his classical theory of mesons to include a treatment of the dipole moment, and shows that all the infinities can be removed. The cross-section for the scattering of neutral mesons by neutrons calculated from this theory agrees with the quantal result for small energies, but is much less than the latter for high energies, decreasing as the square of the energy. The result shows that the theory does not lead to Heisenberg explosions when proper account is taken of the damping forces.

In a note on the nature of oxide films on alloy steels, A. G. Quarrell criticizes the reasoning on which T. Tokumitu based his conclusion that the natural oxide film formed on stainless steel is α-$(Fe,Cr)_2O_3$. Recent application of the high temperature electron diffraction technique leads to the suggestion that the oxidation resistance of heat-resisting steels may be due to the formation of a stable spinel oxide which undergoes no lattice changes on heating and cooling.

F. G. Baddar finds that *o*-α-naphthylbenzoic acid and *o*-4′-methyl-1′-naphthylbenzoic acid give on ring closure a mixture of a benzanthrone and a benzfluorenone. Interaction between diazotized methyl anthranilate and β-methylnaphthalene gives *o*-2′-methyl-1′-naphthylbenzoic acid.

R. Pulver and F. Verzár, in continuation of their experiments on the role of potassium in carbohydrate metabolism, show that in yeast cells intake of potassium is simultaneous with glycogen formation, and that with the breakdown of glycogen potassium is again liberated. This agrees with their previous findings on the role of potassium in carbohydrate metabolism in animals.

RESEARCH ITEMS

Age and Sex in New Guinea Skulls

In a study of skulls from New Guinea, now in the Field Museum of Natural History, Chicago, by W. D. Hambly (Anthrop. Series, **25**, 3, 1940) attention is directed to certain conclusions in regard to age and sex emerging from craniometric investigation of the material of 222 skulls. 28 are excluded as juvenile. Of the remainder, 70 are female and 124 male, distributed into southern and northern groups. In the southern group a high mortality in both sexes occurs in the age-period 20–30 years, accounting for about 46·4 per cent of the population. There is a noticeable decline in mortality at the age of 30–40 years, the rate falling to 12·5 per cent, but with a rise for 40–45 years, though for survivors there is a fair expectancy of reaching 50 years. About 16·7 per cent females and 15·8 per cent males pass the 50-year mark. In the northern group the rate in the years 20–30 is high, that of females reaching 65·4 per cent in the years 20–25. For males and females together from 20 to 30 the rate is 54·3 per cent. From 30 to 40 the rate is 13·8 per cent, with a fair expectancy of reaching 50 years. The survivors of this age number 18·8 per cent. The explanation may be taken reasonably as the more dangerous pursuits of the men (war and head-hunting) and the child-bearing of the women in the earlier period. In regard to differentiation of sex characters in the crania, males have greater cranial capacity, a longer, broader skull, and greater dolichocephaly than the females. They have also greater cranial height, a longer vertical arc and greater arcs over glabella, ophryon, and from nasion to opisthion; but in three respects, namely, nasal index, facial index and facial angle, the difference between male and female population is not so well emphasized. Comparison of craniometrical data from East Africa, Australia, New Guinea, and New Britain suggested a considerable admixture of Negro traits in the Pacific regions. There are mathematical grounds for believing in the probability that Tasmanians are an Australoid-Melanesian people.

War-time Mortality in London

The issue of the *Lancet* of April 20 contains an interesting study by Dr. Percy Stocks, medical statistical officer to the Registrar-General, of the mortality during the first seven months of the War, or more precisely from July 1939 until March 1940. He points out that a very substantial saving of life at ages under five years was the chief explanation of the remarkable fall in mortality from pneumonia, bronchitis, diarrhœa and whooping cough. Moreover, the expected epidemic of measles did not take place. Although children of school age did not benefit from school closure and dispersal to the same extent as children of pre-school age as regards mortality, deaths from diphtheria, measles and whooping cough sank to a very low level. On the other hand, during the winter period young adults showed a remarkable increase in mortality which was mostly caused by respiratory tuberculosis, respiratory diseases (other than pneumonia) and heart diseases, but the deaths from pneumonia did not increase appreciably during the severe weather. There was also a very decided increase in mortality among adults over 45 during the cold weather of January and February, mainly due to respiratory and heart diseases, but the proportionate increase in pneumonia was much less than that for influenza, bronchitis and other respiratory diseases. In conclusion, Dr. Stocks shows that under black-out conditions the increase in deaths due to this cause was least in the weeks when there was a full moon and most serious during the two preceding weeks.

Bird Migration and Gonad Development

From certain experiments, Rowan concluded that birds released when their gonads were at winter minimum or spring maximum showed no inclination to migrate, and that migration was associated with recrudescence or regression of gonads. The suggestion has been tested by Albert Wolfson, who contrasted experimentally the actions of migratory and resident races of juncos (*Condor*, **42**, 93, March–April 1940). The experiments were carried on over two years, and were devised and executed with thoroughness. Juncos were trapped before the period of migration, and were kept in large cages until the wild migrants had departed and were nesting and probably incubating in their northern breeding haunts. Histological examination of samples of the retained birds showed that by this time the gonads were fully developed. When released the resident and migratory races behaved differently; the former remained and were constantly recaptured in the neighbourhood, the latter disappeared, and were not seen or recaptured until the time when the wild migrants returned in the following autumn. Rowan's theory, therefore, does not meet the case, and the author, in a series of critical comments on Rowan's experiments and conclusions, indicates just where in his opinion these failed to give an accurate interpretation.

Parthenocarpy

Considerable practical importance is attached to the fact that the ovaries of various fruits may be stimulated to development by foreign pollen quite incapable of effecting fertilization, so that seedless fruits may result. Sadao Yasuda has been studying this subject since 1928 and has recently published a general account of his experiments (*Mem. Fac. Sci. and Agric.*, Taihoku Imperial University, **27**, No. 1; Dec. 1939). Ovaries of egg plants gave fruit with Petunia pollen but the reciprocal cross is without effect; similarly tomatoes arose from action of the pollen of the egg plant but the reciprocal cross would not work. Various combinations were thus tested, and successful combinations for parthenocarpic fruits showed no connexion with the systematic position of the plants. It was shown that if pollen could germinate and the tubes penetrate deeply into the style, parthenocarpy resulted. The growth of the pollen tubes seems influenced by a special substance in the style; this substance is produced originally in the ovary, a point checked by ingenious experiments with grafted styles. Where the pollen tube can influence ovary development the effect is produced before the tube reaches the ovary; it is only necessary that the tube should penetrate deeply into the style. Ovaries can grow into seedless fruit if injected with extracts of suitable pollen grains. Pollen grains of the proper species, too old to fertilize ovules and give seeds, may still contain this fruit-producing stimulus and may thus induce seedless fruit production.

Origin of Wheat

S. N. PATHAK (*J. Genetics*, 39, 437–467 ; 1940) has examined cytologically several species of Triticum, Ægilops, Secale, and Oryza. The morphology of the chromosomes shows that *T. monococcum* and *T. Ægilopoides* alone contain two pairs of *Sat* chromosomes—all the other species had one pair of these chromosomes with secondary constrictions in common. The number of nucleoli corresponds to the number of secondary constrictions and satellites: there are four in the diploid and tetraploid and six in hexaploid species of Triticum and Ægilops and two in diploid *Secale cereale*. The presence of four satellites and a quadrivalent in *T. monococcum* indicates that the basic chromosome number 7 is a derived one. Five is believed to be the original basic number of this group of species. It is suggested that *Triticum vulgare* may have resulted from a cross between *Ægilops squarrosa* and a tetraploid wheat. It is shown that one of these, *Triticum durum*, has dissimilar chromosome sets corresponding to the *A* and *B* genoms and has probably been derived from a diploid Triticum species with one pair of *Sat* chromosomes and an Ægilops species having secondary constrictions.

Seed Coat Colour in the Bean

H. A. K. LAMPRECHT (*Hereditas*, 26, 65–99, 279–304; 1940. *Z.I.A.V.*, 77, 186–194) describes the genetics of the various colours and markings of the seed coat of *Phaseolus vulgaris*. The striped, marbled and sprinkled coat colours are shown to depend on the multiple allelomorph series *Rrs-Rma-Rst-R-r*. The genes formerly designated *M* and *S* are thus shown to be allelomorphic with *R* and *r*; linkage tests show that the *R* series is strongly linked with the seed coat colour gene *C*. Heterozygous *Cc* or heterozygous *Rr* seeds are marbled and are naturally inconstant. Several genes, *Arc*, *Bip*, *diff*, and *exp*, have been found to affect the distribution of colour. They show incomplete dominance, therefore intergrading types are frequent. Dots of colour on the seed coat is due to a recessive gene *punc* or to a dominant gene *Mip*. The latter controls the distribution of colour around the micropyle. Rough seed coat is due to a recessive *asp*. The recessive gene *mar* causes the presence of a ring of colour around the hilum when another gene *j* is present. It is shown that *mar* always causes the appearance around the hilum similar to that of *J*. Thus recessive *j mar* simulates the effect of dominant *J* in that region.

Linkage Studies in Barley

D. W. Robertson and O. H. Coleman (*J. Genetics*, 39, 401–410 ; 1940) describe two new chlorophyll-deficient seedling types in barley which are determined by the genes *or* and *y* respectively. These genes are placed by linkage experiments in group I with cross-over percentages of *or-f* 8·69, *f-y* 0·81, *y-v* 31·27 (*f* gives chlorina seedlings and *v* gives six-rowed barley). Therefore, three seedling lethal factors are placed close together and at some distance from the non-six-rowed – six-rowed determining gene.

Smut Fungi of the Sugar-Cane

THE taxonomy of smut fungi which attack the sugar-cane has been somewhat uncertain in the past. Dr. B. B. Mundkur has, however, recently studied a considerable range of fresh and herbarium specimens of the fungi, and reaches the conclusion (*Kew Bull.*, No. 10 ; 1939) that the smut upon the culms of sugar-cane consists of one species, *Ustilago scitaminea*, and two new varieties, *U.s. Sacchari-Barberi*, and *U.s. Sacchari-officinarum*. Detailed descriptions of these organisms, and of *U. consimilis*, which also occurs upon the same host, are given.

Photochemical Oxidation of Hydrogen

AN investigation of the photochemical oxidation of hydrogen in hydrogen-oxygen mixtures with light of 1719–1725 A. at 1140–95 mm. pressure, by H. A. Smith and A. Napravnik (*J. Amer. Chem. Soc.*, 62, 385 ; 1940), shows that, with increasing oxygen content, the quantum yields of ozone increase while those of hydrogen peroxide and water decrease. At lower pressures the formation of water shows chain characteristics. The formation of ozone has a negative temperature coefficient in the range 25°–280°, while the temperature coefficients for the formation of water and hydrogen peroxide are positive and may increase with great rapidity above 230°. The results are interpreted on the assumption that the primary photochemical reaction is $O_2 + h\nu = 2O$, followed by interaction of oxygen atoms with oxygen and hydrogen molecules, the first by triple collisions: $O + O_2 + M = O_3 + M$, and the second by triple collisions with an oxygen molecule as third body: $O + H_2 + O_2 = H_2O + O_2$. The possibility of hydrogen as the third body is not excluded. The oxygen atoms may also react with hydrogen molecules: $O + H_2 = OH + H$, the hydroxyl radicals reacting with hydrogen to form water and atomic hydrogen: $OH + H_2 = H_2O + H$. The atomic hydrogen reacts with a mixture of hydrogen and oxygen at room temperature to form hydrogen peroxide, first forming HO_2 by a triple collision: $H + O_2 + M = HO_2 + M$, and the HO_2 may react in the gas phase or on the walls to form hydrogen peroxide: $HO_2 + HO_2 = H_2O_2 + O_2$.

New Supernovæ

DR. J. JOHNSON of the California Institute of Technology reports from Mount Palomar the discovery, on a photograph of February 16, 1940, of "a new object, star-like, not moving, about 13th magnitude, located at the southern tip of the edge-wise spiral NGC 5907". Plates taken with an 18-in. Schmidt camera on February 18 and March 1 confirm the reality of the object, which is presumably a supernova. The parent nebula is well placed for northern observers now and for the next three or four months. Harvard Announcement Card 519 helps in fixing the time of outburst by stating that at the position given no object brighter than magnitude 14·6 shows on the patrol plates of February 3, and none brighter than magnitude 13·2 on February 11. Dr. F. Zwicky reports that he has found a supernova of apparent magnitude 16 on a film taken with an 8-inch Schmidt telescope on Palomar Mountain on December 4, 1939. It is in the spiral nebula at R.A. 0h. 54m., S.Dec. 5° 20′ (1939·0) and is about 16″ north-west of the nucleus. It is presumed that it attained a maximum brightness, mag. 15, on November 20. The spiral in which it appears is estimated to be seven million parsecs distant.

VOLCANISM IN FRENCH SOMALILAND

M. E. AUBERT DE LA RÜE has recently travelled extensively in French Somaliland (November 1937–May 1938) for the purpose of conducting field work, which he has since examined critically (*Bull. Volcanolog.*, ii, 5, 71–108; 1939). It is very plain from the report that volcanism has had an important role in the building up of this region of tropical Africa near the Gulf of Aden. At the moment there is no active volcano in the land but in numerous places there are fumeroles and hydrothermal springs which are the last stages of volcanic activity. In order of age (oldest first) the volcanism may be roughly classified as: (1) Old Basaltic Series, (2) Rhyolitic Series, (3) Recent Basaltic Series, (4) very recent eruptions, and (5) present day volcanic phenomena which include (*a*) fumeroles and (*b*) thermal springs.

The Old Basalts in the form of dykes and lava flows were incident after the deposition of the Infracretaceous sandstones. They were observed by M. Dreyfuss in the Ali Sabien mountain complex and they have been observed in the Mabla mountains by M. Dreyfuss and M. Teilhard de Chardin. M. E. Aubert de la Rüe has been able to identify them over a much wider area. In the Issa area they form the base of the Guelileh Valley, and they may be seen under the rhyolite flows of the dissected plateau of Damer-Kada. The Boura mountains, previously considered entirely rhyolitic, in reality have a basaltic base which in places attains an altitude of 750 metres and which is surmounted by tuffs and rhyolitic lava flows. In the Dankali area the Old Basalts appear at the base of the rhyolitic Hassa-Ali chain. They are to be found at the entrance to the Orgoïta Ravine at the foot of the Yagueri Mountains a little to the north of the Yoboki Pass. The series from the base upwards consists of Old Basalt, greenish rhyolitic tuff, rhyolitic obsidian, and rhyolite. In places the basalts attain an altitude greater than 1,000 metres. This is so in the high valley of Magaleh and at the col Adhali-Daba to the north of Tadjourah, where they reach a height of 1,140 metres. This Old Basaltic Series is often greatly altered, containing siliceous concretions, calcite veins, zeolites, stillbite and heulandite. When not decomposed the basalt presents a very varied appearance in different localities.

The Old Basalts are followed by the Rhyolitic Series, the age of which is uncertain because there are no sedimentary rocks interstratified with them. M. E. Aubert de la Rüe has been able to show that at least in some places the rhyolites were produced before the basaltic eruptions had ceased. One such case is in the Mabla Mountains where, under the path from Letabolo to Baté-Ero, one can see a rhyolite flow about 10 m. thick between two basalt flows. The Rhyolitic Series may be observed throughout the colony, and does not appear to have a greater thickness than 500 m. The rhyolites, in places prismatic and very fresh, are elsewhere frequently altered. The obsidians are opaque or translucent, grey, grey-green, or black, the latter often having been mistaken for coal. Pantellerite and comendite, described by Lacroix and Arsandaux, have been found near Hol-Hol and in the Mabla Mountains.

The lava flows may be compared with the 'coulees stratoïdes' of Yemen described by M. P. Lamare, and have often been eroded into extremely steep pitons. The centres of eruption are most difficult to determine and the different 'Massifs' are regarded not as the vestiges of ancient volcanoes as in the region near Aden but as the remains of rhyolitic plateaux. This agrees with the opinion of P. Lamare, to whom the Mabla massif appears to be a horst.

The rhyolitic series is followed by the Recent Basaltic Series, but in between the deposition of the two was a long interval of time during which a good deal of erosion took place. This may be seen at a number of places but particularly in the valley of Magaleh in the Goudah massif where the whole sequence may be observed. The Recent Basaltic Series appears to be due to a series of fissure eruptions which took place with great regularity. Here and there, between two of the lava flows there exists a well-cemented, reddened conglomerate usually containing pebbles of basalt but sometimes pebbles of rhyolite. The series is fairly uniform, fine grained, and generally having a doleritic texture. It nearly always contains olivine but never in great quantities. Occasionally it is porphyritic with large phenocrists of plagioclase. Some Andesitic flows, chiefly in the Arta massif and near the Koranke-Hada-E-Kouri-Djabet Mountain, accompany the Recent Basaltic Series. The thickness of the lava in the flows usually varies from 3 m. to 5 m. There are no intercalated tuffs to separate the flows but Aubry found in the Assal Basin under 200 metres of labradorite a lacustrine sedimentary deposit with Unio, Corbicules, Limnées, Planorbes and Mélanies about three metres thick. Similar phenomena have been observed elsewhere in the colony. The smallish volcanic cones visible from Djibouti in the region to the south-west have been formed by scoriaceous lavas and are of mixed Strombolian–Hawaiian type. Perhaps Mount Garbi is a volcanic cone, and if so it is the largest in French Somaliland (1,650 m.).

It is difficult to draw a demarcation line between the Recent Basaltic Series and the very recent eruptions, but it is probable that man was already on the earth when the volcanoes of Ghoubet-el-Kharab erupted. The basaltic flows, interstratified with the Quaternary cones of dejection at the lower end of the slopes of the Mabla Mountains, are probably fairly recent and have been affected by very recent faults in the valley of west Ababoléï. The last stages of volcanic activity may be found in the fumeroles and hot springs now existing. A typical fumerole is in the south-east of the plain of Hanleh about 3 km. 500 m. to the east-north-east of Garbes. It is called by the Danakils 'the smoking mountain' and consists of a band a few score metres wide and about 400 metres long orientated in a north-west–south-east direction. In this region the basalt has been largely decomposed to a red clay which is often at a temperature of 100° C. Aqueous sulphurous vapour at 100° C. escapes from the ground through a multitude of small fissures sometimes silently and at other times with a slight whistle. Near the region there are incrustations of white gypsum, saccharoïde and kalinite.

There are numerous regions with hot springs in the colony. A typical one is at Asbahalto on the eastern bank of Lake Abbé, called by the Danakils 'the evil smelling water'. Here innumerable thermal springs have deposited walls of travertin which have the appearance of ruins, about 5–10 m. high on the average. This travertin is composed chiefly of calcium carbonate together with a little magnesium carbonate. Superficially it is clear grey whilst in the interior it is yellowish white, having a spongy structure and being somewhat friable. The denticulated walls and small pitons are aligned roughly east-west and probably follow the fault lines. A spring at the foot of Badikoma has a temperature of 100° C., gave a fairly alkaline reaction and when evaporated left a residue of 2·48 gm. per litre. This consisted of silica 0·090 gm., calcium carbonate 0·109 gm., calcium sulphate 0·485 gm., magnesium chloride 0·032 gm., potassium chloride 0·054 gm., sodium chloride 1·648 gm., sodium bromide 0·0035 gm., together with organic and miscellaneous material 0·0585 gm. Other hot springs abound in the plain of Hanleh, in the valley of west Kouri, in Goum, Halol, and in Obock.

FOREST PRODUCTS RESEARCH BOARD

THE report for 1938 of the Forest Products Research Board recently issued (London: H.M. Stationery Office, 1939. 1*s.* 6*d.* net) is dated June 1939. Remembering that the outbreak of war was to come so soon after its completion, there are one or two points which appear to merit particular mention. The chief, perhaps, is the research on composite wood, for which the Board had had under consideration detailed proposals for the provision of equipment.

The interest which this subject has aroused would seem to indicate that all the substitutes which have replaced wood have apparently had little influence upon the great demands still being made on the forest. The Board's report states, with reference to composite wood: "We are impressed with the need for systematic research on the properties of this class of materials in order to build a foundation of technical knowledge such as has been accumulated in the case of 'solid' wood by many years of work at various universities and laboratories in the past." In view of the importance which the processes of manufacture and the interrelations of the materials used have on the properties of the final products, the need for systematic research is evident. New methods of test and investigation may have to be developed to deal with these products, the properties of which differ fundamentally from those of 'solid wood'. Inquiries regarding these products were rapidly increasing, even though the laboratory has disclaimed possession of any real technical knowledge of them. The industries interested cover every field in which natural wood has hitherto been used, and several in which the use of wood has practically been abandoned.

The report of the Director of Forest Products Research is issued with the above. Inquiries in every department of the Laboratory's activities continued to be numerous. As one example of the work undertaken, the experimental work on the production of charcoal in portable steel kilns is proving successful. Charcoal is being increasingly used for various industrial purposes, particularly in the manufacture of Rayon; and the manufacturer in Great Britain has been very dependent on foreign supplies of it. Hitherto, charcoal which has been made in portable kilns has contained too great a percentage of volatile matter; the experimental kiln now in use is said to go far in removing this objection. A leading firm of Rayon manufacturers has stated that charcoal produced by certain burnings is equal to the best obtainable from any source.

CORTICAL LOCALIZATION OF INTELLIGENCE

H. M. HILDRETH, at the meeting of the American Association for the Advancement of Science, Columbus, Ohio, December 1939, presented a statistical study of the cortical localization of intelligence.

The problem involves the correlation of an independent physiological variable with a dependent psychological variable. Since in studying human beings it is not possible to destroy predetermined parts of the cortex by operation, an experimental group of individuals whose brains had been damaged by disease or by natural organic changes had to be used. The psychological variable could be measured by using well-established tests of intelligence. The group studied consisted of individuals found to be suffering from cerebral arteriosclerosis, in which disease small areas, apparently occurring at random, are destroyed throughout the brain. From a psychopathic hospital of 4,000, all the patients who after complete examination were found to be suffering from this disease were selected, and from this group were eliminated those who showed signs of any disease, for example, brain tumour, that might conceivably affect intelligence. This gave a selected experimental group of 201 subjects. A control group of 201 normal individuals was also selected, comparable except that they had no signs of arteriosclerosis. Previous records of intelligence and school attainments were available.

It is argued that if all the subjects are now given an intelligence test, since the two groups are matched, then the performance of the normal group might be taken as what the other group would have been if it were not suffering from arteriosclerosis.

To find out the effect of the disease the two groups were compared in the various Binet tests, the frequency and percentage of each group passing the given tests being tabulated and the percentage of deterioration on each test calculated.

On the hypothesis that the ability to pass a given test is cortically localized, a randomly distributed deterioration would be expected. Such was not the case. The experimental findings supported the hypothesis that intelligence is a function of the whole brain, against the hypothesis of specific localization.

LONDON'S WATER DURING 1938

THE recently issued report of the Metropolitan Water Board* tells of the unceasing supervision exercised over London's water supply during 1938. The total output from the Board's works was 111,438 million gallons, a slight increase over the previous high record of 1937, the average daily supply to consumers being 312·77 million gallons, of which 65 per cent was derived from the Thames.

Some 50,000 samples were analysed during the year, of which about 30,000 were routine bacteriological, and 4,700 routine chemical, examinations, the main purpose of which is to determine that all the processes—storage, filtration, purification, distribution—are working satisfactorily so as to ensure a pure and safe supply to consumers. Based upon the *Bact. coli* test, 99 per cent of all samples were of first-class quality (absence of *Bact. coli* from 100 ml.) —a highly satisfactory record.

Of researches conducted in the Board's Laboratories, much attention has been directed to improving the *Bact. coli* test, and the method for isolating coliform organisms when present, for the purpose of differentiating the type. New procedures were also investigated for improving the method of isolation of *Clostridium Welchii* and the Streptococcus organisms that are sometimes of service for assessment of the potability of a water.

The occurrence of *Bact. paratyphosum* B, a microbe that causes a form of enteric fever, in Epping sewage has been noted since 1931. This specific organism is still present in the sewage, in fact was somewhat more numerous than it was in 1937, and as a precaution chlorination of the effluent has now been established as a permanent measure. Investigations on improved methods for the isolation of this organism are in progress.

Complaints are sometimes received concerning the taste of the water, and no less than 11,360 'taste' tests were carried out during the year by the expert tasters of the Board's staff. Complaints of taste are generally attributable to some defect at the works, the commonest being an overdose of chlorine. Earthy or musty tastes result from decomposition of, or fungoid growths in, filter bed skins during hot weather, and characteristic tastes are produced by decomposing plankton. In one instance, a musty taste occurred in the water drawn from the cold water tap in a kitchen, and was traced to two species of fungi growing in the tap. Organisms belonging to the Actinomyces are capable of producing earthy tastes, and this subject is under investigation.

Certain algæ and diatoms are subject to periods of sudden excessive growth, and are liable to cause trouble in reservoirs and filter beds. Thus, it was reported that a 'brown' growth had arisen in one of the reservoirs, and microscopical examination showed that this was caused by excessive growth of a diatom, *Stephanodiscus Hantzschii*, which was clogging the secondary filter beds. By treatment with alum this trouble was overcome. Investigations are being carried out in the Biological Section with the view of ascertaining the cause of these fluctuations in the number of the algal and other living forms in the water; they may depend upon peculiar variations in the silica, phosphates and other mineral constituents of the water which are known to take place at certain seasons of the year. An account is given of the appearance in a reservoir of *Oscillatoria rubescens*, a blue-green alga, and of the chemical conditions prevailing. In August when this organism became very numerous, *p*H values were higher, temporary hardness was lower, and concentrations of PO_4 were rising rapidly to a very high level compared with March, when the organism was scanty.

Notes are given on the occurrence of certain rare Copepods and other forms of microscopic life, numerous tables are included, and the report is illustrated with several excellent plates.

ECONOMICS OF WAR COSTS

THE problem of paying for the War is discussed in an Oxford Pamphlet on World Affairs (Oxford: Clarendon Press. 3*d*. net) by G. Crowther and a broadsheet issued by Political and Economic Planning (P E P), which have both appeared under that title. The real problems of paying for the War, the broadsheet points out, are economic, political and psychological; for the limits of war effort are not financial but social, psychological and economic. The size of the output of war material depends on the willingness of people to work harder and make their capital resources last longer, and above all, on the way they react to reductions in their standards of life. The methods of financing the War are vitally important, since they determine the distribution of its cost between different groups of people and may have a profound effect upon the distribution of income after the War. The best method can only be decided after a careful examination of social claims and resistances, and once the method is decided financial technique can be used to implement policy.

The P E P broadsheet, taking the national income of Great Britain as £5,700 millions, and the current national expenditure at more than £2,500 millions, points out that the increased revenue must be drawn from increased production, the use of overseas assets and the diversion of output. Mainly it will be a burden for the present. Diversion of output from capital maintenance is estimated as offering savings from £300 to £500 millions, while for the diversion of resources from the production of goods for private consumption varying estimates are given. The four main methods by which the Government can gain control over the resources which it needs are taxation, borrowing, through the medium of the price mechanism and by direct Government control.

In regard to taxation, the broadsheet points out that the bulk of additional income tax revenue must come from the middle incomes, where its incidence is comparatively light, and the importance of devising a comprehensive family allowance scheme is stressed. Reviewing other taxation possibilities, the scope for a tax on luxuries is indicated ; the inevitable heavy taxation of those with low incomes will be resented unless the Government makes it quite clear that those who are comfortably or luxuriously off are being taxed in earnest. Discussing Mr. Keynes' proposals for forced saving by paying a proportion of all wages and salaries in the form of a blocked deposit not available for spending until after the War, the broadsheet points out that the scheme offers a means of preventing standards of living from rising, or of reducing them without incurring major political opposition. Further research into the limits of the voluntary type of saving is also required.

In regard to borrowing, the raising of loans directly from the public is not inflationary, but borrowing from the banks is almost bound to be inflationary. This is the third method by which the Government can gain control of the requisite resources, and both the broadsheet and Mr. Crowther point out the objections to inflation. Mr. Crowther urges that we should first concentrate on raising taxation to the highest supportable level on rich and poor alike. We should then see what could be done by rationing to increase the genuine savings that can be borrowed. Only when we have exhausted these deliberate and scientifically planned devices should we turn to the haphazard, incalculable and inequitable method of inflation. Certain measures of Government control over the economy are an indispensable adjunct to inflation, such as price control and its corollary rationing.

Mr. Crowther argues that the fundamental task of war finance is to transfer resources from consumption to the purposes of war, and he insists that, while totalitarian war cannot be financed entirely out of taxation, the only taxes likely to bring in sums substantial enough to contribute to avoidance of inflation are not confiscatory taxes on the rich or fancy taxes on profiteers, but plain honest taxes that hurt plain honest people. Moreover, since the real economic necessity of war is to reduce consumption, even after the ordinary man has paid his taxes, his consumption must be further restricted, either by voluntarily or compulsorily increasing his savings or through the cost of living rising against him.

SEVENTY YEARS AGO

Nature, vol. 2, May 26, 1870

The Admiralty have acceded to the request of the Royal Society by again placing Her Majesty's surveying steam-vessel the *Porcupine* at their disposal for another deep-sea expedition. A photometric apparatus has been contrived by Mr. Siemens to ascertain the depth to which solar light penetrates the sea.

The Duke of Devonshire, the Marquis of Lansdowne, Sir John Lubbock [Lord Avebury], Sir James Kay-Shuttleworth, Bernard Samuelson, Dr. W. Sharpey, Prof. T. H. Huxley, Prof. W. A. Miller and Prof. [Sir] G. G. Stokes have been appointed to make inquiry with regard to Scientific Instruction and the Advancement of Science, and to inquire what aid thereto is derived from grants voted by Parliament or from university and college endowments, and whether such aid could be made more effectual.

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned :

Temporary Lecturer (woman) in Education and Psychology—The Principal, Municipal Training College, Cottingham Road, Hull (May 30).

Lecturer in Mathematics, and a Senior Mistress for the Day School—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham (May 31)

Head of the Women's Department of the Blackpool Technical College—The Director of Education, Education Offices, Stanley Buildings, Blackpool (May 31).

Head of the Chemistry Department—The Principal, Municipal Technical College, Hopwood Lane, Halifax (May 31).

A Representative to superintend and co-ordinate the work of the British Council in Bulgaria, Rumania and Yugoslavia—The British Council, 3 Hanover Street, W.1 (June 1).

Two Teachers (men) of English for Yugoslav-British Institute Belgrade—The British Council, 3 Hanover Street, W.1 (quoting 'Belgrade') (June 1).

Lecturer in Biology—The Secretary, Technical College, Sunderand (June 3).

Lecturer (male) of Physics—The Clerk to the Governors, Northern Polytechnic, Holloway, N.7 (June 3).

Assistant Woman Graduate for Commercial Geography in the Schools of Technology, Art and Commerce, Oxford—The Chief Education Officer, Education Offices, 77 George Street, Oxford (June 4).

Male Lecturer in English at Oporto University, Portugal—The British Council, 3 Hanover Street, W.1 (quoting 'Portugal') (June 5).

Head of the School of Architecture and Building—The Registrar, School of Architecture and Building, College of Arts and Crafts, Leicester (June 7).

Inspector, Southern Education—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1, (quoting 'Inspector, Southern Education') (June 15).

Mathematical Tutor in the Khartoum Secondary School—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1 (quoting 'Mathematical Tutor') (June 15).

Lecturer in Chemistry in the School of Science, Khartoum—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1 (quoting 'Lecturer in Chemistry') (June 15).

Lecturer in Electrical Engineering, and a Lecturer in Mechanical Engineering, at the School of Engineering, Khartoum—The Controller, Sudan Government London Office, Wellington House, Buckingham Gate, S.W.1 (quoting 'Lecturer in Electrical or Mechanical Engineering') (June 15).

Head of the Chemistry Department—The Clerk to the Governors, Technical College, Normanton Road, Derby (June 15).

Curator of the Museum and Art Gallery—The Town Clerk, Town Hall, Leicester (endorsed 'Curator') (June 17).

Chief Fisheries Officer, Palestine—The Director of Recruitment (Colonial Service), 29 Queen Anne's Gate, S.W.1 (June 22).

Teacher of Physics at the Rugby College of Technology and Arts—The Principal and Organizer of Further Education in Rugby, 61 Clifton Road, Rugby.

Temporary Graduate Assistant (man or woman) to teach Physics at the County Technical College, Dartford—F. L. Notley, 11 Essex Road, Dartford.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Saturday, May 25

BRITISH PSYCHOLOGICAL SOCIETY (at 55 Russell Square, W.C.1), at 3 p.m.—H. W. Durant: "A Critical Account of Public Opinion Measurement".

At 5.30 p.m.—J. G. W. Davies: "Individual Differences between Psychological Workers".

At 6.15 p.m.—Alec Rodger and Patrick Slater: Report on "Some New Non-verbal Tests".

Monday, May 27

ROYAL GEOGRAPHICAL SOCIETY, at 5 p.m.—A. Stephenson: "Graham Land and the Problem of Stefansson Strait".

Tuesday, May 28

ROYAL INSTITUTION, at 5.15 p.m.—Prof. V. H. Mottram: "Food and the Housewife".*

Thursday, May 30

BRITISH INSTITUTE OF RADIOLOGY INCORPORATED WITH THE RÖNTGEN SOCIETY, at 2.30 p.m.—Physical and Biological Experiments with Neutrons. Dr. John Read: "The Production and Measurement of Neutron Radiation at the Mount Vernon Hospital"; Dr. F. G. Spear: "A Comparison of the Biological Effects of Neutrons and Gamma Rays"; J. C. Mottram: "The Action of Neutrons on the Growth of Bean Roots and upon the Mitosis of Bean Root Cells"; Dr. L. H. Gray: "Survey of Results so far Obtained by Different Workers"; Discussion.

At 6.30 p.m.—Annual General Meeting.

AUSTRIAN ACADEMY IN GREAT BRITAIN, at 5 p.m.—Prof. Dr. Ernst Freund: "Austria's Contribution to the Solution of Cancer Problems".

Friday, May 31

ROYAL INSTITUTION, at 9 p.m.—Prof. W. W. C. Topley, F.R.S.: "Bacteria in the Air".

"THIS FREEDOM"

THE menace to freedom of thought and learning not merely in Europe but throughout the world has grown unmistakably graver with the latest advances of ruthless aggression. In Belgium and Holland pitiless destruction is spreading in countries which possess traditions representing even more richly than German history the most colourful, creative and imaginative phases of European life. To the lengthy list of centres of learning where creative thought and independent inquiry and research have already been proscribed there are now to be added such names as Brussels, Leyden, Louvain.

No one who has the least appreciation of the debt which science alone owes to research at Vienna, Prague, Warsaw, Cracow, Copenhagen or Oslo can contemplate without dismay the further extension of the list of those centres of learning whose work has in this way been closed down or stultified. "Achievement in science," as Raymond B. Fosdick, president of the Rockefeller Foundation, remarks in his review for 1939*, "more often than not is the result of the sustained thinking of many minds in many countries driving towards a common goal. The creative spirit of man cannot successfully be localized or nationalized. Ideas are starved when they are fenced in behind frontiers. The fundamental unity of modern civilization is the unity of its intellectual life, and that life cannot without disaster be broken up into separate parts."

It is well indeed that the president of the Rockefeller Foundation should refer so plainly to the disastrous consequences even to the intellectual life of America which would follow from the interruption, or suspension for half a decade, of the fundamental activities of the universities and laboratories of Europe as a result of exhaustion or chaos through the War. The onslaught on Holland and Belgium has a further significance. Beyond the achievements in politics and culture of the Low Countries, these peoples, now under German rule, have in the past given noble service to the cause of liberty. Twice at least in history the effort of the Dutch was decisive in the struggle against the domination of Europe, while in recent years both Holland and Belgium have brought to modern politics the best qualities of that city life which stirred the imagination of the Middle Ages and the Renaissance. They have built up communities in which democratic self-government is respected as an ideal and practised as a mode of life.

The passion for liberty and the belief in toleration live no less ardently in the hearts of these peoples to-day, as their heroic resistance has borne witness. What is new in the situation is the comparative inefficacy of that intellectual or moral resistance to-day in the face of the immense material power which can be exerted by a nation barbarous enough to turn its whole national economy to preparation for war, and ruthless enough to disregard all the generous principles and traditions upon which Western civilization is based. As Edouard Herriot reminds us in the "Wellsprings of Liberty", to-day it is imperative to recognize that "Thought and action are two sisters who must never be separated".

For scientific workers, the stirring lines of J. R. Lowell's Harvard Commemoration Ode are as pregnant with meaning in the present struggle as when they were first recited seventy-five years ago. Once again the service and quest for truth are no longer sufficient within the walls of a laboratory or university. They must be rendered over wide fields of national need under stress and strain and peril of life itself. Lowell's eloquent third stanza may well remind us that the struggle in which we are engaged is one which enlists the sympathy and goodwill of all those who are concerned with the quest for truth, the patient, unprejudiced unravelling of the secrets of Nature, the maintenance of learning, of freedom of investigation, and of creative thought, whatever their nationality.

---

* The Rockefeller Foundation. A Review for 1939. By Raymond B. Fosdick. Pp. 72. (New York: The Rockefeller Foundation, 1940.)

That the reality of the challenge to the finest values in our intellectual heritage is recognized as frankly in the United States as in Europe is shown beyond question in Dr. Fosdick's review. In an admirable passage he traces the intimate relation of European and American science and the interdependence of intellectual leadership. But he goes far beyond this. Pointing out that we are living in a world which threatens to brush aside everything that intelligence stands for, he brings us face to face with the real challenge of force.

Force, he insists, in the end always defeats itself. It appears to cut through the complexity and confusion without the necessity of the severe intellectual effort and discipline involved in the creation of an effective alternative. In the long run it solves nothing and answers nothing, and the surrender to force in practice, while rejecting it as an ideal, is one of the real tragedies of our times. The great society which science and culture have placed within our reach will not be achieved by the application of force, but by the persistent application of intelligence against the things that now dwarf our hopes. In the interdependent society we have created, the issues are no longer simple, individual and local; they are complex, social and world-wide, and beyond the experience of most of us. Money and credit, international relations, trade and finance, national income and its distribution, wages, profits, prices, purchasing power, savings and investment, employment, social security, collective bargaining, housing, propaganda, public administration, relations between Government and business, individual and social adjustment, social welfare, education, population—these are only a few of the urgent issues demanding creative and sustained intelligence for their solution.

With no less compromise than Lord Halifax in his address, the "Challenge to Liberty"*, Dr. Fosdick brings us face to face with the real issues involved in the present struggle. Lord Halifax sees the conflict between youth and youth through the acceptance of sharply differing standards of conduct in different countries. He sees that there is an active force of evil which unless fought and overcome will rapidly reduce our civilization to a desert of evil, and he insists that if we are to keep our bearings we must base ourselves firmly on social, moral and religious standards. If we are to recapture the secret of order for international society we must as individuals strive to erect or maintain standards that will bring true freedom through the way of discipline.

If the doctrine of force could be effectively put to shame the way would be open to concentrate the effort now mobilized for war upon the improvement of the common lot of man. What matters first is that we should desire not an easier but a better world, and equip ourselves in body, mind and spirit to create it. We must recognize that we have first to overcome the doctrine which denies the corporate claim to liberty of men and women organized in national societies and refuses the even more fundamental claim of men and women to the free expression of human personality, which rests upon the eternal value of every human soul. The future of humanity cannot be left in the hands of those who would imprison and enslave it.

It is well that the fundamental issues should be laid so clearly and unmistakably before us, not merely by British leaders but also by those in the other great Anglo-Saxon nation. If war jeopardizes our heritage and interrupts our normal intellectual activities, we must remember that it also affords fresh opportunities for creative work and reconstruction. As Miss Dorothy Sayers puts it, we can 'begin here' in the task of creating the new society if we are prepared to make the effort.

It is indeed on this note of opportunity that Dr. Fosdick concludes his review. In place of letting conflict degenerate into a mere fight for power, we can maintain the creative struggle for facts and ideas by vigorously supporting competent intellectual efforts to define and analyse the issues facing society. When by objective and competent study the issues are more precisely defined and the facts more exactly known, the conflicting views which still remain can, with reasonable good will, more readily be resolved. A firmer substructure for public and private policy will thus be provided, and the clear statement of the highly involved issues from the technical side is a first step to the clarification of the moral and ethical questions of to-day.

---

* The Challenge to Liberty: an Address given at Oxford. By Viscount Halifax. Pp. 24. (Oxford: Clarendon Press; London: Oxford University Press, 1940.) 3*d*. net.

For such reasons, Dr. Fosdick considers that studies in the social sciences present an intellectual challenge of central importance; and his appeal for adequate support, for the development of the highly specialized and complex methods necessary by highly skilled men and women working under the most favourable conditions, no less than his searching analysis of the handicaps under which the social scientist at present works, merits the close attention of the scientific worker even at the present time of crisis and strain. Unless we surrender the idea or resolve of victory, we must face now the issues involved in the ordering of a new society in which creative intelligence and human personality find full expression. We must free our social scientists to think with all possible penetration wherever their thinking may lead, and assist the minority of pioneers whose work in the social studies is reaching up to new levels of scientific achievement.

Intense as may be our immediate concern with our war effort, we must still spare thought for the future if that effort is to reap its full reward. We may still attempt the removal of those handicaps on social investigations to which Dr. Fosdick refers —the establishment of a sound balance between the extension and the transmission of knowledge in this field, the extent and manner of endowment of social research, the training of the social scientist on broader lines, and the establishment of effective relations between the social scientist and the world of action which is his laboratory. The solution of the problems confronting society is the task of all its intellectual and moral agencies. Society may, however, fairly expect of the social scientist that as part of his contribution to our war effort he should be objective and technically competent, and deepen and make more definite our understanding of fact and relationship in the social world.

Nor are these words for the social scientist alone. It is well to be reminded in this fateful hour of the supreme values for which we contend, the importance of creative thought and of the free expression of human personality. We may well be grateful that there are those of our race across the Atlantic who see so clearly as Dr. Fosdick the real issues before us, and can define the task with a lucidity and precision which at least hint at comradeship in its discharge.

PRACTICAL SCIENCE IN SCHOOLS

THE publication of a communication from Mr. A. G. Lowndes, formerly biology master at Marlborough College, on page 863 of this issue raises a problem which has for long exercised heads of schools and administrators: the problem is whether the money spent on science laboratories and their equipment is justified by the results achieved, especially in the teaching of biological science. Essentially this problem resolves itself into two parts: first, what is the aim of science teaching, and secondly, how may this aim be best achieved?

The aims of science teaching have been well stated in the Spens Report; to give pupils some knowledge of natural laws and of their application; "to reveal the influence of scientific thought and achievement in the evolution of our present day civilization"—an appeal to social interest and social utility; and to give an introduction to scientific methods of thought and investigation. There can be little disagreement among science teachers on these aims; they are, indeed, those which have been held to be valid for so long as science has been a subject in school curricula. There is, however, some disagreement on how they may be achieved; for it has in the past been widely held that practical laboratory work is essential. Impetus to this view was given by Prof. H. E. Armstrong, whose influence on the teaching of science at the end of the last century was profound, and who insisted that pupils must be placed in the attitude of discoverers, and must, therefore, be given opportunities for discovering, in the form of a laboratory and apparatus. Sir Percy Nunn has expressed this view thus: "to make our pupils feel, so far as they may, what it is to be, so to speak, inside the skin of the man of science, looking out through his eyes as well as using his tools, experiencing not only something of his labours, but also something of his sense of joyous intellectual activity". In its official publications, the Board of Education has frequently stressed the importance of practical work in science, but has invariably qualified this by pointing out that other methods of presentation are complementary.

There is considerable difference between the practical work possible in physical science and that in biological science. The metrical aspect of physical science (as taught in schools) makes laboratory work comparatively easy to arrange and organize with large classes, and there is a wealth of experiments which can be completed in the space of a double school period. In biological science much more time has usually been spent on observation and laboratory technique (notably dissection and section cutting), and much of the experimental work occupies days and even weeks before conclusions can be reached. There are, however, physiological experiments which can be carried out without taking up excessive time, for example, on plant and animal tropisms and on bacterial cultures.

The attempt to get pupils "inside the skin of the man of science" by means of practical laboratory work cannot be said to have been wholly successful. Dr. Michael West (*Educational India*, 6, No. 4; 1939) has stated that "it is perfectly possible for these expensively educated children to pass right through a school science course and remain at least fifty years out of date in scientific knowledge, to be ignorant indeed of all that really matters in the science of to-day". Much the same view is expressed by Prof. J. D. Bernal, in "The Social Function of Science", in a reference to the report of the Science Masters' Association on the teaching of general science: "Only in the last year year does the outlook become modern, but even then nothing later than 1890 is introduced"; and, "The chemistry is worse; the whole course contains nothing not known in 1810." Bernal also stresses that nearly all practical work in schools is "either preparation, measurement, or description, all operations essential to science but by themselves entirely insufficient".

There is evidence from American research that factual knowledge and knowledge of scientific method can be imparted as successfully by demonstration as by practical work, and demonstration certainly has the advantage of being less expensive, in time and money, and of setting a standard of work which is not achieved when pupils themselves carry out experimental work. Nor need demonstration be didactic, for every learner is encouraged by the skilful teacher to play a part, by suggestions and observations, in the demonstration as it proceeds. In this connexion the Spens Report mentions that "by a greater use o good demonstration we believe that scienc teachers will more commonly stimulate wonde and imagination".

That the place of practical work in the biology syllabus is being subjected to increasing criticism is borne out by the fact that recently a strong representation from the teaching profession ha suggested to certain examining bodies that th amount of practical work in the syllabus shoul be considerably diminished, and that failure i practical work at the examination should no longe involve failure in the biology examination as a whole.

It is not suggested that all practical work should be jettisoned, but rather that the warning issued in 1933 by the Board of Education in "Science in Senior Schools" should be heeded: "Many schools are in danger of falling into superstition and treating practical work as a ritual." A new stimulus to real scientific investigation, involving purposeful practical work, has come from the development of rural activities in an increasing number of schools, particularly public elementary schools. Wherever a garden is maintained, and wherever live-stock is kept (poultry and pigs are popular), real problems capable of scientific solution by pupils at once crop up. How to obtain the maximum yield from a soil as yet unanalysed; how to feed a pig in order to obtain the maximum weight at a certain age; how to house hens so that they are healthy; these and kindred problems involve observation, measurement, recording and, most important, *planning* and the proper use of controls. (At least one influential university teacher has stated that his scholarship pupils seem often unable to *plan* their experimental work.) The problems arising out of rural activities are susceptible to laboratory treatment, though the laboratory may sometimes be out of doors; they are real first-hand problems, with educational, social and utilitarian values, which cannot equally be said to be true of the routine experiments so frequently carried out in school laboratories.

A final point to bear in mind, especially during present circumstances, is the difficulty in obtaining material (especially biological) for laboratory examination and experimentation. This difficulty has always been present and never satisfactorily solved. Now is the time, therefore, to tackle this problem, not as a temporary measure, but with the view of eliminating the necessity of at any rate certain kinds of material altogether.

THE STONE AGE OF MOUNT CARMEL

The Stone Age of Mount Carmel
The Fossil Human Remains from the Levalloiso-Mousterian. Vol. 2. By Theodore D. McCown and Sir Arthur Keith. Pp. xxiv + 390 + 28 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1939.) 63*s.* net.

THE human remains described in this very important and voluminous work come from two neighbouring caves—the biggest, et-Tabūn (Levels B and C), and the other a mere rock shelter, Mugharet es-Skhūl (Level B). The first, a big cave, is at the mouth of the Wady Mughara, looking down on the coastal plain. The second is a little above the foot of the valley, slightly upstream and on the same bank as the first.

The excavations, carried out jointly by the British School of Archæology in Jerusalem and the American School of Prehistoric Research, were directed during six years work (1929–35) by Miss D. Garrod, with various fellow-workers, Mr. Theodore McCown taking her place during one year when her health obliged her to rest. It was during this year that the greater part of the site of es-Skhūl was examined (continuing the work previously begun) and that, in a breccia as hard as building stone, most of the graves were discovered.

Et-Tabūn was excavated by Miss Garrod on her return, while Mr. McCown, with the help of Sir Arthur Keith and of the staff of the Royal College of Surgeons of England, devoted himself to the very laborious task of freeing, preparing, restoring and studying the very important remains from es-Skhūl. This work began in 1933 and finished with the publication of the present big volume; not too large, since the remains of Quaternary man studied were adults as well as children of both sexes: three almost complete skeletons with their skulls in a good state of preservation; five less complete with their skulls crushed, a single leg and sixteen other fragments from Skhūl. Tabūn produced only one complete skeleton, a mandible and other isolated fragments. The approximate ages of these individuals are given as four, five and ten years, five people between thirty and forty, and one of about fifty.

Although, except for some slight remains in a final Acheulean level at Tabūn, all the rest of the human remains are associated with a Levalloiso-Mousterian industry, they are not exactly contemporaneous. Those at Skhūl came with a fauna in which bovine animals predominated, and those of Tabūn with one in which the gazelle was most common. But these differences are not far apart in time, so that these funerary remains can be considered as almost contemporary.

Very different characteristics distinguish the human types, Tabūn I possessing many Neanderthalian traits, and the men of Skhūl exhibiting all the transitional features leading from the Neanderthal to the Neanthropic Cro-Magnon type.

The authors think that the human type of Mount Carmel was subject to variations greater than those of any living human group; so much so, that, if it were not for the intermediate types seen even in the same level, these variations might be considered as two distinct races, one akin to the Neanderthal and the other to the Cro-Magnon. Having examined the question as to whether it was interbreeding of the two which produced these intermediate types, the authors reject that idea and prefer to consider it as an example of a human group in a crisis of mutation.

These leanings towards a Neanderthalian type produce a strain more resembling that associated with the Central European interglacial Krapina, Ehringsdorf and Steinheim type, rather than the Rhenish or French Neanderthalian. As for the skulls, many are like the Neanthropic group of Předmost, but they have far more Cro-Magnon traits. If, by the forehead, ribs, vertebræ and teeth (though the ribs are flattened as in Neanthropic man) the people of Mount Carmel may be classed, like the Galilee skull which is of the same race, as Neanderthalians, by the height of the man of Skhūl (1 m. 70 cm. and 1 m. 78 cm.), and the characteristics of most of the limbs (not of all, for some are more Neanderthalian), these Palestinians have chiefly Cro-Magnon traits.

This all goes to support the theory of Hrdlička (1927), who held that the Cro-Magnons of Europe descended from the Neanderthalians of the same continent. But, though this may be possible, according to the authors' ideas, it is too simple an explanation, and in any event severe glacial conditions cannot be evoked as the discriminating factor, since in Palestine there were pluvial and not glacial periods. Still, it is true that a transitional human type is found there, leading from one race to another. They are not proto-Cro-Magnons, but proto-Caucasians, their cousins.

The authors then pursue their detailed analytical comparative study in Chapters iii–xxii, treating successively the foot, leg, thigh, pelvis, vertebral column, thorax, shoulder girdle, hand, fore-arm,

arm, dentition, mandible, facial and cranial characteristics of Skhūl V, of Tabūn I, of Skhūl IV, then IX, II, VI, VII, and the brain of Skhūl I as reflected in the endocranial cast.

In a review such as this, one cannot follow the authors in their innumerable comparative tables and measures, and we pass to Chapter xxii, "An Analysis of the Structural Character of the Mount Carmel People", producing twenty-five points of comparison between the Neanderthal, Palestinian, Mount Carmel and Cro-Magnon peoples. This shows that the Palestinian of Mount Carmel has only three points in common with Neanderthal man (frontal torus, shape of the malar, pattern of the teeth): eight points in common with the Cro-Magnon and twelve which are intermediate. Comparing 86 other details of unequal importance, the authors arrive at a total of 111 characteristics examined: 16 are Neanderthalian, 32 Neanthropic, 46 intermediate, 13 indeterminate and 4 special. But if most weight is attached to details concerning the teeth, eyebrow ridges, shape of the cheek-bone, the sphenoid and certain metacarpal bones, and the many intermediate characteristics, the authors think that the Palestinian of Mount Carmel should be classed as genus Palæanthropic, but forming the link with the genus Neanthropic.

AN ANALYSIS OF THE STRUCTURAL CHARACTERS OF NEANDERTHAL, MOUNT CARMEL AND CRO-MAGNON MAN

Neanderthal Man	Mount Carmel Man	Cro-Magnon Man
Stature, short but stocky.	Men tall, women short, or of medium stature.	Men tall, women of medium stature or small.
Head massive with the facial parts large relatively to the brain-containing part.	Head massive, but face not excessively developed.	Head massive but not excessively developed.
Skull dolichocephalic or mesaticephalic.	Most are strongly dolichocephalic; but one Tabūn woman has an index of 77.	Most are strongly dolichocephalic.
The vault is very low (platycephalic).	Vault of medium, or even above, medium height.	Vault high.
Eyebrow ridges assume form of continuous torus.	Torus, but with a tendency to separate into median and lateral parts.	Separation into median and lateral parts is complete.
Forehead very receding.	Forehead moderately full.	Moderately or fully developed.
Occiput *en bourrelet* compressed vertically, does not project behind attachment of neck.	Not compressed vertically. Projects slightly beyond attachment of neck.	Compressed laterally. Projects well behind attachment of neck.
Face—particularly the upper face—very long.	Face of moderate, or above moderate, length.	Face of moderate length.
Face prognathous.	Face usually orthognathous.	Face orthognathus.
Malar bone has the flat form seen in anthropoid apes.	Malar is flat and anthropoid-like, but with a decided tendency in some individuals towards a Neanthropic form.	Malar is Neanthropic.
Superior maxillæ are devoid of canine fossæ and are snout-like in form.	Superior maxillæ, although devoid of fossæ, are flattened in front but not snouted.	Neanthropic.
Orbits are large and rounded in form.	Orbits wide but not high.	Orbits wide but not high.
Nose very large, projecting and wide, its lateral marges not demarcated from face.	Nose variable in projection and width; laterally it is partially demarcated.	Nose variable in projection, usually narrow; laterally sharply demarcated.
Subnasal part of face is deep and wide.	Subnasal area wide, but not deep.	Subnasal area moderate in width and depth.
Mandible robust.	Variable, some robust, others if large yet not robust, some small but stoutly built.	Moderate in development both in size and strength.
Chin absent or rudimentary.	Chin absent, or of moderate development.	Chin moderate or well developed.
Ascending mandibular ramus very wide.	Width varies, in some very wide, others of moderate width.	Width varies, some very wide.
Mandible, in the region of the angle truncated or flattened.	Angle moderately developed.	Angle moderately or well developed.
Teeth are big.	Teeth are moderate in size or large.	Teeth moderate in size.
Molars retain certain primitive characters.	Molars retain certain primitive characters.	Molars are Neanthropic in characterization.
Spinal column and its vertebræ present pithecoid characters.	Spine and vertebræ possess certain Neanderthaloid features; others are Neanthropic.	Spine and vertebræ are Neanthropic.
Adaptation to the upright posture and to bipedal progression less perfect than in Neanthropic man.	Adaptation to bipedal progression apparently as perfect as in modern man; cervical curvature probably less developed than in Neanthropic man.	As in Neanthropic man.
Lower limbs short.	Lower limbs long.	Lower limbs long.
Mean cranial capacity about 1,400 c.c.	Capacity in 3 adult males ranges from 1,518 c.c. to 1,587 c.c.; one woman (Tabūn) 1,271 c.c.; one woman (Skhūl) about 1,300 or 1,350 c.c.	Capacity large.
In form the brain shows primitive or simian features, particularly in the small size of frontal lobes and in convolutionary pattern.	Neither in size nor in form of lobes is there a decided difference from brain of Neanthropic man. Convolutionary pattern, so far as our evidence goes, was simple.	Lobes large and well convoluted.

It is still an open question whether the woman found in Tabūn I, who is the most Neanderthalian of all those found, represents a different race, and what is her place in time compared to the people of Skhūl. The few remains found either in the Acheulean or neighbouring overlying levels have certain characteristics which make it difficult for the authors not to class them as older than the people of Skhūl. They consider the Tabūn type older, though this has been contradicted, for on p. 265, where the character of the Tabūn woman's skull is compared with those from Skhūl, we read: "Cranial characters support the view, already founded on a comparison of their skeletons, that they represent different types or breeds of humanity, and yet breeds of the same stock. In the Skhūl cranium there are many Palæanthropic features, but these are overshadowed by those of a Neanthropic character. In the

Tabūn cranium it is the opposite, the Palæoanthropic features vastly preponderate over the Neanthropic." The author of this part of the text remarks on the close relationship between the female skull of Tabūn I and the Neanderthalian skull of Gibraltar, although it differs by certain Neanthropic features such as the angle of the skull's development, a rise in the vault and flattening of the sides of the skull. The conclusion is that "the Tabūn woman represents a separate race of the Neanderthal type, the difference between the Tabūn and Gibraltar skulls being of approximately the same amount as that which distinguished the skull of a European from that of a negro".

We quote the summing up: "We find it very difficult to believe that these are mere individual anomalies; they have all the appearance of intrinsic structures of morphological value. Only future discoveries can resolve the problem of her position—whether an individual sport, or a representative of a distinct race."

As I heard Prof. Boule say, speaking of the Palestinian man: "The complexity of evolution amongst human types, as new discoveries are made, and this one in particular, far from simplifying the problem, appears little by little to present us with new ones, still insoluble".

I would add that, in spite of the enormous progress and the sensational discoveries which have been made in modern times, such as those in Palestine, Chou-Kou-Tien and Java, Palæanthropic anthropology is still necessarily 'in the making'. It cannot be otherwise, for we must remember that, though we are fairly well informed about the human types contemporary with the last interglaciation, and later times, we know extraordinarily little of what took place during the two preceding interglacial epochs and the intervening glaciations, though these represent more than sixty per cent of the time that man has existed.

In spite of everything, a certain law of gradual development becomes more apparent each time, and however much we hesitate over such problems, they grow clearer each day, showing us human types less and less removed from anthropoids.

H. BREUIL.

EVOLUTION AND FATS

The Chemical Constitution of Natural Fats
By Prof. T. P. Hilditch. Pp. xi+438. (London: Chapman and Hall, Ltd., 1940.) 35s. net.

THE fats constitute a large group of natural substances. They are present in plants and animals on land and water, both salt and fresh; they represent an important ingredient of our food. To the chemist they are compounds of glycerol with fatty acids, long straight-chain carbon compounds in an ascending series of numbers from C_{14} to C_{24}, increasing by two carbons at a time. Nature has curious devices, eccentric habits; one of them is to ring the changes with relatively few substances, combined together in different ways, so as to produce a vast number of different fats, that is glycerides, characteristic of individual plants and animals. The process is akin to the infinite number of melodies which the pianist can produce on a few notes.

The devices of Nature have to be discovered in the laboratory; they cannot be reasoned out in a dark room until sufficient data have been accumulated to justify the setting up of a theory, which is only then of value when it leads to new experiments. The nature of animal fats was first established by Chevreul in classic researches published in 1823; it is noted that he was a determined enemy of charlatanism in every form. Since then, research on the fats has gone on in laboratories throughout the world, and the accumulated knowledge provides material for many volumes. Nowhere has the search been more diligent or more successful than in the laboratories at Liverpool under the leadership of Prof. T. P. Hilditch. He has devised new experimental technique of much higher accuracy, and accumulated data as to the nature of some six hundred natural fats.

Valuable as is such work in itself, it acquires new interest when chemical structure can be related to biological source. The monograph before us is written with this intent. Science proceeds on the assumption that the world is intelligible, and we may claim that it is an achievement to establish a relationship, a sequence, between the nature of the fatty acids present in fats and the biological development of their parent organisms.

The connexion was developed in outline in NATURE in 1936 (**137**, 479) in an article by Hilditch and Lovern, but it is of sufficient importance to give it a paragraph. The most widespread of natural fats is oleic acid; the major saturated acid is palmitic acid with sixteen carbon atoms. In freshwater life, C_{16} and C_{18} acids predominate, but in salt water there is both greater unsaturation and a high proportion of acids up to C_{24}—nearly 30 per cent in marine fish.

Coming on land, there is a simplification in the number of fatty acids, there being a definite gradation through the amphibians, reptiles and birds to the domestic animals, which is largely in parallel with the course of evolution traced by the biologist. It is to be expected that a change in external character indicates a change in chemical architecture, but it could not so easily be predicted that the change in the fats would parallel evolution,

It is a triumph for the learned doctors of chemistry,

"Profoundly skilled in analytic,
Who can distinguish and divide
A hair 'twixt south and south-west side."

Plant fats, as has long been known, sometimes contain as major constituents a specific unusual fatty acid confined to one or at the most only a few of the natural plant families: plants seem to have the urge to be enterprising and try chemical syntheses on their own. Another fact relating to plant fats is the relation between saturation of the acid and climatic temperature: in cooler climes linseed oil is as a rule more unsaturated.

The monograph is arranged so as to bring into prominence the component acids of fats. It contains chapters on the component glycerides, on the chemistry of the acids and on experimental technique. It is a storehouse of knowledge, a guide to future experimentation and a stimulus to the reader. A philosopher condemns science because it enthrones the measuring, weighing, calculating faculty of the human creature. The achievement described here may be set against such criticism. E. F. ARMSTRONG.

BOILER WATER TREATMENT

Boiler Feed Water Treatment

By F. J. Matthews. Second edition, revised and enlarged. Pp. 319+16 plates. (London: Hutchinson's Scientific and Technical Publications, 1939). 12*s*. 6*d*. net.

WHEN this book was originally published in 1936, it was pointed out by the author that while the great developments which had recently been made in the methods and apparatus for boiler feed water treatment had been very advantageous for those in charge of the larger steam plants, they had created a problem for the small operator who has not at his back all the facilities which exist at the big power stations, but is forced to worry out his problems for himself. In relation to feed water treatment, the problem is to know what is the right thing to do in a given case, for, without clearly stated principles and well-substantiated practical guidance, it is difficult for the average technician to exercise a fair judgment as to the appropriate system, and to ascertain if all goes well when his choice of plant has been installed.

Generally speaking, three courses are open to the boiler operator: the use of one of the proprietary softening agents, the installation of a lime-soda plant, or the adoption of the zeolite or base-exchange system. The purpose of this book, therefore, was to provide such practical information as would place him in a position to be able to choose and operate a water-softening plant with intelligence and efficiency. The author deals with the subject in a logical sequence which will greatly appeal to the practical man as well as to the student and chemist. He describes the various types of natural waters, and explains in what respects they prove unsuitable for use as boiler feed. Proceeding then to operating troubles, he gives first the older corrective measures and then, by setting out their failings and insufficiency, brings into their proper perspective the later improvements which have been effected. Four main aspects of water treatment and its bearing on boiler operation are dealt with, these being scale formation, corrosion, foaming and priming, and finally analysis and routine testing. From this method of presentation there emerges for the reader a clear picture of the purposes served by each process or combination of processes.

In this enlarged edition a considerable amount of revision is apparent, bringing the information up to date and in line with the results of recent research. Caustic embrittlement, one of the most serious problems of the boiler-house engineer in recent years, is treated in considerable detail, and the numerous contributory causes, preventable and unavoidable, are set forth. Among other new features are the subjects of colloidal conditioning, the Budenheim process, electrical scale prevention and the avoidance of turbine deposits. For students, the selected references at the end should also prove a valuable addition.

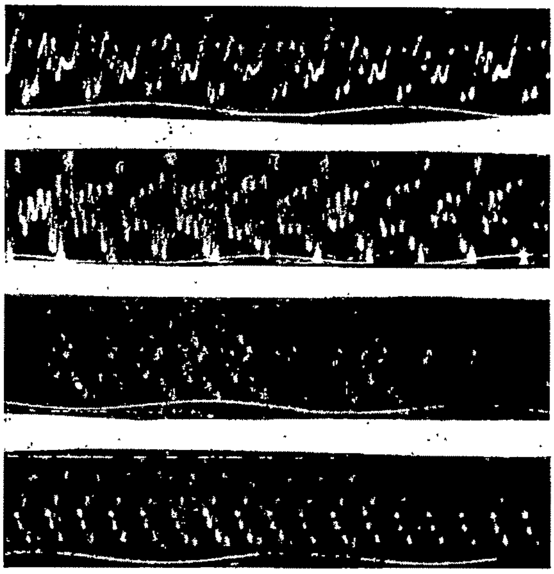
RECENT WORK IN EXPERIMENTAL PHONETICS

By Dr. E. G. Richardson,
King's College, Newcastle-on-Tyne

It is now ninety years since Scott with his phonautograph—the precursor of the gramophone—first made traces of the wave forms of speech sounds. The mechanical wave-tracers progressed and reached their peak of development in the phonodeik of Miller, but they have been largely superseded by electrical recorders. The talking film and the cathode ray oscillograph have found their way into the phonetics laboratory, and the physicist has been called in to assist the philologist in the scientific study of speech forms. Such a team of workers operating an experimental phonetics laboratory (such as that of King's College, Newcastle-on-Tyne[1]) can carry out useful work in the classification not merely of standard English speech forms, but also of local variants, which may be preserved in the form of gramophone or film records to remain, perhaps as museum pieces, when all speech has been reduced by education and broadcasting to a dull uniform 'standard English'. To this end a number of linguists are exploring the country districts of Great Britain, where special forms die hard, with portable recording equipment, to persuade the older people to "say something into the microphone".

Any points which require detailed examination may be pursued further in the laboratory, where by means of electrical pick-ups or photo-electric cells the wave-form characteristic of a vowel or consonant may be selected and projected on to the screen of the cathode ray oscillograph. By such means, for example, it is possible to distinguish the Northumbrian 'burr' or guttural *r* from the frontal *r* which the French adopt, even when it occurs in rapid speech so that the distinction might fail to be detected by a sensitive ear.

Such deductions cannot be made without certain safeguards, and it is here that the co-operation between scientist and linguist is most helpful. On one hand, the philologist is apt to be mazed by the elaborate convolutions in the wave-form of a simple vowel—and even to the physicist, it seems a big step from the wave-form of a tuning-fork to that of a vowel; on the other hand, the scientist, in his desire to attach a label to every sound, is liable to read into the record sounds which are not there. For example, a record has been published of the wave-form of the word *farmers* with a section ascribed to the central *r*, which is never pronounced in normal English speech.



Wave-forms of the vowel ɑ at frequencies of 104, 129, 150 and 208 c./sec. respectively. (Photo by W. Riddell.)

Amid a vast accumulation of such records, it is pertinent to inquire how much can be learned from speech wave-forms. How far can the sound ɑ be recognized as such, when uttered by different persons or by the same person in different circumstances? The difficulty is enhanced when one reflects that vowel sounds are not quantized, but range over an infinite number of fine gradations; so that how many distinct vowels should be recognized and where their boundaries lie are matters hotly contested by the philologists themselves. The problem is being tackled in the King's College laboratory by making collections of oscillograph records of the same vowel enunciated at a series of pitch values.

A set of such records of the vowel ɑ by a male voice is reproduced herewith. The characteristic pattern of this vowel—a series of peaks diminishing in height within the period—can be recognized in each trace, although analysis of each trace into its acoustic spectrum scarcely helps the identification. It reveals not only a change in the fundamental pitch but also, accompanying each fresh setting of the vocal cords, the intrusion of sufficient harmonics of the fundamental to disguise in the spectrum the fact that the same vowel is being enunciated throughout the set.

Changes in the spectrum also occur when the intensity is altered, the pitch remaining constant. The general effect of singing the vowel more loudly is to throw more of the energy into the higher partials. This is what might be expected of any form of musical instrument. It is shown, for example, in the timbre of the clarinet played at a fixed note with rising blowing pressure.

Of course, one must not overlook the psychological aspect of these tests. Someone, either the speaker or a listener, has to judge whether the task set—to enunciate the same vowel at different values of the fundamental pitch or of intensity—has been faithfully carried out. Actually, it is difficult to keep these two changes—of pitch and loudness—separate, the general tendency of a choir being to raise the pitch of a note which it is asked to sing more loudly, particularly if it is unaccompanied by an organ or orchestra. There is, however, more behind this than a mere psychological exhilaration on the part of the singer or speaker. Our vocal apparatus is such that it is physically impossible to sing a given vowel over a wide range of intensity. Certain vowels also having important partial tones low in the musical scale cannot be truly elicited at a high pitch. Female singers especially have to make a compromise with such vowels sung at a high pitch, though the context provided by the neighbouring consonants usually suffices to convey the meaning of the words so altered.

Other variations in the wave-form of a vowel may be introduced by the consonant which precedes or follows it. With the exception of the so-called voiced consonants, these sounds may be likened to those which occur during the attack on, and relinquishing of, a steady note by a musical instrument; such sounds as the biting of the bow upon the violin string and the tonguing of the flute by the player. It has recently been shown by J. W. Black that these transient speech sounds have little influence on the vowel sound which follows or precedes them, during the period that the vowel holds the field. (The same applies to mechanical instruments of music.)

Minor deviations from what one may regard as the standard form of the vowel occur during the sustained singing of it or even within the few seconds which it occupies in conversational speech. The 'tone' of the muscles which put tension upon the vocal cords, the 'blowing pressure' within the lung-bellows, the setting of the mouth resonator; these are not rigidly set in the human instrument as they are, for example, on the organ while a key is held down. It is not surprising, therefore, to find slight fluctuations in the wave-form from one period to the next during the enunciation of one and the same vowel. The strips of film reproduced in the figure would not exactly overlay other strips from the same films ten feet farther on, but such deviations would appear of little significance compared to the variations between the four films shown. Some philologists make much of these variants within the record of a vowel. E. W. Scripture indeed goes so far as to consider that they invalidate any application of Fourier analysis to the wave-forms of vowels.

Nevertheless, there is hope for the view that to each vowel a definite wave-*pattern* may be attached. Moreover, the majority of recent research favours the 'formant' theory of vowel sound production. This regards every musical instrument as being composed of a resonator or system of resonators coupled to an exciting or maintaining agency. In the human voice the exciting element is located in the vocal cords, while the cavities of the mouth, nose and sinuses form the sound-boards. The setting of the exciting agency at a definite fundamental frequency will give rise to a sound, the acoustic spectrum of which will be rich in those resonances which happen to march with the fundamental exciting frequency or its attendant harmonics. This formant of resonances—or 'wolf notes' as the violinist calls them when they are undesirably prominent on his instrument—is an individual characteristic. On most mechanical instruments and, for that matter, in the voices of animals like the cow and the dog, the formant is fixed, but man has learned to change these sound-board resonances by subtle gradations whereby the different vowel sounds may be recognized by an interlocutor.

The existence of a formant proper to each vowel is the cause of such variation of the wave-pattern with pitch as is shown in our figure. Of course, there are certain portions of the vocal resonators which remain unchanged in size and therefore in frequency as the speaker readjusts his cavities for another vowel, and these have been recognized in the acoustic spectrum of most of the sounds uttered by an individual in normal health. They are as characteristic of the adult individual as his finger-prints. The formant theory is supported by the possibility of synthesizing vowel sounds out of models constructed of a generator coupled to variable resonators, as in the well-known work of Sir Richard Paget with mechanical models on one hand, and that of Dr. W. H. Eccles and Prof. G. W. Stewart with electrical models on the other.

Another feature which characterizes speech is intonation—the variation in intensity and pitch which a person puts into a speech. Compare, for example, the level monotone of an Italian announcer in the broadcasting service with the excessive modulation of his Swedish confrère ; or the stolid utterance of the Somerset man with the lilt of the East Anglian or Northumbrian. This is a characteristic which may readily be measured on inexpensive electrical apparatus of the noise meter and beat-frequency types. Both these instruments incorporate some form of valve-voltmeter in their final stages, the deviations of which from a mean setting (of intensity and frequency, respectively) can be recorded as a flickering of the needle, or, better still, as the root mean square value of the deviations. The latter figures can be obtained if some form of wattmeter in the output stage is used, and may be taken as a measure of intonation, in the same way that the root mean square value of the deviation from a standard stream velocity is taken in hydrodynamics as a measure of the intensity of turbulence in the stream.

Nor must the physiologist be left out of this work. Though experiments on the vocal apparatus of dead mammals played a part in the early development of phonetics as an experimental science, results so obtained are rather discounted as criteria for the science of the human voice to-day. Much, however, is to be learnt from X-ray photographs of the larynx taken when set in position for the production of a sound, which is oscillographed at the same instant. Such studies are being made by—among others—Prof. O. Russell in America and Dr. R. Curry in England.

Other work which should prove of great import to linguistic studies involves the taking of high-speed cinematograph pictures of the motion of the vocal cords as seen through the laryngoscope. Such photographs, in various modes of action of the cords, normal, falsetto, etc., are now being obtained in the laboratories of the Bell Telephone Company at New York.

PLANNED WHEAT PRODUCTION

BY SIR JOHN RUSSELL, F.R.S.,

ROTHAMSTED EXPERIMENTAL STATION

WE have in Great Britain nothing quite like the Food Research Institute of Stanford University, California, which periodically publishes important monographs on foods, and in consequence it would have been difficult to produce here the comprehensive study "Competition among Grains" recently issued by Dr. Jasny. Mr. Paul de Hevesy's achievement in completing his great work "World Wheat Planning* is therefore all the more remarkable, and he is to be congratulated on having brought together in one volume an enormous mass of data relating to the production of wheat in the different countries of the world, its distribution and its consumption. The labour involved has been prodigious, but it is known that he has been engaged on this work for a long time, and his extensive knowledge of the subject is well recognized.

Wheat, like sugar, affords an example of the triumph of politics over Nature. Both crops grow admirably in the regions naturally suited to them, and these regions are adequate to produce all, and more than all, that the world is likely to require. If they were in fact called on to produce all the supplies, the necessary corollary would be unhampered trade between the producing and the consuming countries. But there is an alternative method. Science has opened up the possibility of growing both crops in conditions not naturally suited to them, and so enabled many countries to produce their own supplies. It is true that the supplies cost more, are less certain and less abundant than by the other method, but in those countries where political considerations have dictated a policy of autarky or self-sufficiency, agricultural science is called upon to make the best of the task of growing a crop in conditions not really suited to it. Two general methods are adopted : the environmental conditions are changed by various devices of soil management, and the plant is changed by cross-breeding and other methods. Sooner or later pathological problems arise, sometimes of great importance : these also have to be dealt with.

Wheat is really a plant of the semi-arid regions : it has been found wild in Asia Minor, northern India, Abyssinia, etc. Throughout long years of cultivation many varieties have been selected or bred, but the crop still retains its semi-arid nature.

The optimum climatic conditions for wheat production are a moderately low rainfall of about 20–25 inches per annum, with dry warm weather for maturation and harvesting. These conditions prevail over great belts of continental areas, especially in North America, Australia, and Eastern and Central Europe, including the U.S.S.R.; in these regions wheat can be grown cheaply and in abundance. England, with its many soils and climates, also has a considerable proportion of wheat-growing regions. The area east of a line from Durham to the Isle of Wight is largely suitable, and another area extends westwards from the southern part of this line; the boundary is roughly the escarpment formed by the Inferior Oolite outcrop. The determining factor is chiefly the rainfall but with soil as a strong subsidiary, for wheat is less easy to grow than grass on a heavy clay soil or than barley on a light one, so that it tends to keep to the loams. It is better suited to heavy than to light soils, and in the old days was much grown on the clays in the eastern counties, the Midlands and the south; for this purpose the land was laid up in high ridges separated by deep furrows, many of which still remain, giving a curious wave-like appearance to the pastures. Their original purpose was to provide drainage, and although modern mole-draining would be much better, the cost of levelling the ground would be more than the land was worth.

---

* World Wheat Planning and Economic Planning in General. By Paul de Hevesy. Pp. xv+912. (London : Oxford University Press, 1940.) 38s. net.

The area under wheat in Great Britain was at a maximum in the early 1870's, when there were 3½ million acres. The total production was probably about 2½ million tons, sufficient for the needs of 19 million people at present rates of consumption (300 lb. wheat per head per annum). The population of Great Britain in 1871 was 26 millions, so that the home production amounted to 73 per cent of the total consumption.

Even in those days there were importations of wheat from America, Australia and Europe, but only by way of completing the home supplies. Then, with almost dramatic suddenness, wheat growing in England become unprofitable. The American and Canadian farmers had been rapidly breaking up the prairies, the railway was pushed across the continent and the trans-Atlantic steamship services were organized. When the chain was completed, wheat was brought over from North America in great quantities and sold on our markets at prices far below the cost of production here and, in some years during the financial crises in the West, below the cost of production there. The politicians of the day decided to leave economic forces alone and so did nothing; English farmers gave up wheat-growing, and a short time before the War we were producing not much more than 10 per cent of our total consumption. Then the Government stepped in, and virtually made a contract with farmers to produce about 15 per cent of home requirements at an agreed price. The actual arrangements were complicated by the fact that the Government did not wish to interfere with the usual marketing arrangements, and so left the ordinary machinery at work, but paid to the farmers the difference between the market price which they had actually received and the contract price which they were due to receive. These are called 'deficiency payments'; they work well enough so far as the farmer is concerned. Unfortunately a section of the Press calls it a "subsidy", which, of course, it is not. Most business enterprises nowadays are worked on contracts, and it would be a very good thing if the system were more widely extended to agriculture.

As a result of the Wheat Quota Act, the nation can count on 15 per cent of its requirements being met at home, and in peace-time this proportion is fairly satisfactory, though a case could be made for a larger one; however, the figure is a good compromise. For there is a very considerable difference between ordinary English and imported wheat: the English wheat does not give the large, well-piled loaf obtainable with the so-called 'strong' imported wheat, and the English housewife, therefore, does not like it and will not buy it. Most of the mills are situated at the ports, and they use in normal times only a small fraction of English wheat: the inland mills use more, especially when they can get the one 'strong' wheat commonly grown in England—Yeoman, produced by Sir Rowland Biffen at Cambridge. English wheat is much used for biscuit-making and for poultry feeding; for both purposes it is admirable. What English wheat lacks in 'strength', however, it more than makes up in power of growth, and the English 'weak' wheats include some of the heaviest yielders known. 'Strength' refers only to the character of the dough, and has nothing to do with vigour of growth of the plant or nutritive value of the grain.

In war conditions, a production of only 15 per cent at home is insufficient, and efforts are therefore made to increase the output here. The chief difficulty is that wheat is one of the less productive crops: it usually gives less than 1 ton per acre of dry matter for human food, while potatoes yield two to three tons of dry matter and mangolds may give double this quantity—this, however, is food for animals. The war-time increase comes from the ploughing up of the less productive grass land, our great national reserve of fertility.

An important reason for relying on importation in peace-time is that wheat is one of the easiest of all crops for the farmers on great continental plains to grow. Their first methods led to severe soil erosion, but where this has not gone too far the modern methods are free from this objection. Wheat is also one of the easiest of all agricultural products to store, to transport, and to sell. In a world permanently at peace, densely populated countries like Great Britain could confine themselves to crops giving larger quantities of dry matter per acre, or to products like vegetables, milk, eggs, high-quality meat and fruit where freshness is an asset.

A cynic looking for examples of human folly could find none better than the human treatment of the bountiful supplies of wheat of the last fifteen years. The nations pray that their daily bread may be given to them, and it has been, with a margin to spare. Mr. Hevesy gives a completely dispassionate and objective statement of the results. During the period 1926–34, the world produced more wheat than it consumed : the margin was only small, and never exceeded 2·5 per cent except in one year, but the continued small over-production made the markets so sensitive that prices fell to ruinous levels. Since most of the world's population is engaged in agriculture this loss of purchasing power by farmers and farm workers led to serious industrial and financial depression. The over-production did not arise from heavy yields, but from an extension of acreage partly in Europe as a consequence of the self-sufficiency policy.

Countries that lived in part on their wheat exports—Canada, Australia, the Argentine—had to subsidize their farmers to save them from bankruptcy, while countries that aimed at self-sufficiency found themselves obliged to export temporary surpluses at shipwreck prices, paying the normal price, however, to their producers. Mr. de Hevesy instances a country where 25 million quintals (92 million bushels) excess were produced at an average cost of 19 gold francs (that is, the Swiss franc before its devaluation in September 1936) per quintal which had to be exported at 6–7 francs, the difference being made up by the taxpayer. Yet the small percentage excess that was causing all the trouble was not really superfluous : millions of people in Europe and other countries were under-nourished, but the attempts made at Geneva and elsewhere to persuade nations to buy more bread-and-butter failed.

The trouble was intensified by fiscal arrangements. An inquiry showed that during 1929–30 consumers paid 66,000 million gold francs for their bread, but the growers received only 36 per cent of this total; most of the remaining 64 per cent went in taxes.

There were considerable indications of a further wheat crisis ahead had not the War brought on a still greater crisis. The "Big Four"—the United States, Canada, Argentine and Australia—were last August discussing the possibility of arranging for quotas, and after agreement they intended to hold a wheat conference in London to be attended by the U.S.S.R. and the Danubian countries. The War stopped this, but Mr. Hevesy thinks more wheat crises, with all their attendant evils, are inevitable until world wheat production is planned and organized.

Much of the book is occupied with a full description of wheat production in all countries from which any information can be obtained. In a particularly interesting section on Germany it is pointed out that, prior to the War, Germany was one of the foremost wheat-importing countries, but during the period 1931–35 she became nearly self-sufficient and can now, if the harvest is good, produce all her requirements of wheat, rye and other grains. Nevertheless Germany bought some 15½ million bushels of wheat from wheat-exporting countries during the autumn of 1938, and her reserves must now be considerable. The yield of wheat in Germany between 1890 and 1930 increased by about 11 bushels per acre and is now about 32–33 bushels per acre, about as much as our own yield. Gigantic distributing machinery has been set up called *Reichsnährstand*, a kind of cartel including all farmers and their associations, all merchants of agricultural produce, the exchanges and all processing industries. It is organized like the National Socialist Party itself, having in the village its "confidential agents", above these the district leaders, and at the top the chief for the whole Reich ; practically all the officials are members of the Party. It exercises very complete control over farmers, salesmen, millers and all others who handle food production. The farming is based on the Hereditary Farm Law of 1933, setting up about 700,000 hereditary farms which may be inherited by one child only, usually the eldest, who has no power to subdivide, sell, or mortgage the land without a State permit, and if this is granted at all it is only for sale to another farmer.

While the fixing of prices is effectively carried out, there is no such planning of production as in the U.S.S.R. ; it is left to the individual to decide what he shall sow, and this seems to be all that is at his discretion. The Government, of course, influences his decision by the prices they fix. In the end food prices are considerably higher than in England and the standard of living of the people is lower.

In the section on the U.S.S.R., Mr. Hevesy finds no evidence of increased yields since the pre-Revolution days, notwithstanding enthusiastic claims as to what Russian science has done for agriculture ; also he states that the cost of production, so far as can be ascertained, is very high, in spite of the much-praised mechanization and social-economic system. The total production of wheat seems not to have kept pace with the growth of population. However, Russian wheat statistics are complicated by the change which took place in 1933; prior to that date they were based on the grain actually collected; after that date they are based on the "biological" or unharvested crop, a deduction being made for "technically inevitable losses in harvesting". In 1933 the deduction was given as 10 per cent, that is, about 1 bushel per acre, but much doubt has been expressed as to whether the losses could be kept as low; the figures for production are taken by Dr. Schiller as maximum figures which certainly have not been exceeded.

THE HYDROGEN BOND

By Dr. C. E. H. Bawn,
University of Bristol

It has been recognized for many years that under certain conditions a hydrogen atom can form a connecting link between two other atoms. It may be considered as forming a bond between them, known as the hydrogen bond. Although the hydrogen bond is not strong, recent investigations have shown it to be of very wide occurrence. The concept has been extremely useful in explaining the association of polar liquids like water, the association of carboxylic acids, alcohols, amides, etc., the closure of rings within the molecule, and in interpreting many measurements of structure by X-ray and electron diffraction methods and of the frequency shifts of the infra-red absorption bands of certain known groupings. It was investigations of this type that not only established the existence of this form of bond but also provided information regarding the conditions in which its formation is to be expected, and, in many cases, of the actual energy of the bond. In spite of the enormous amount of experimental data now available, there is still much information which is lacking; the exact mechanism of the bonding power of the hydrogen is not clear, and there are many difficulties with questions of terminology.

With the object of clarifying the situation, a general discussion on "The Hydrogen Bond" was held by the Faraday Society on May 17 at the Imperial College of Science and Technology, London. A number of subjects was discussed in the six papers presented to the meeting, but briefly, the discussion can be considered under two headings: (1) the methods of studying hydrogen bonds by infra-red absorption, X-ray diffraction, and magnetic susceptibility measurements, and a survey of the results obtained; and (2) the occurrence of hydrogen bonds in molecules of biological importance, such as the proteins and carbohydrates.

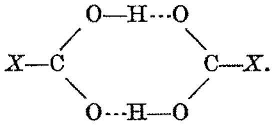
It follows from the quantum-mechanical theories of valency that hydrogen cannot form more than one covalent bond and that the attraction of two atoms as found in hydrogen bond formation must be due to ionic forces. The positive hydrogen ion with no electronic shell around it attracts one anion to its normal internuclear separation, and this could then attract a second anion, namely, $X^-H^+Y^-$. As might be expected, the strength of the bond formed should increase with increase in the effective negative charge of the bonded atoms. Thus fluorine, oxygen, nitrogen, and chlorine should form hydrogen bonds of strength decreasing in this order. Perhaps the best example of this type of ionic bonding is the HF_2^- ion; Pauling considers that this ion resonates among three structures:

$$\mathrm{F\ H\ F^-} \qquad (A)$$
$$\mathrm{F^-H^+F^-} \qquad (B)$$
$$\mathrm{F^-H\ F} \qquad (C)$$

When we come to consider more complex structures involving intermolecular hydrogen bonds, steric requirements must also be satisfied, that is, the interacting groups must be capable of sufficiently close approach to enable the attractive forces to come into play. When we review the conditions of formation of the hydrogen bond, it is not at all surprising that one meets examples of bonds covering a wide range of interaction, from strong bonds to weak bonds, finally emerging into groups of interaction which we know as due to van der Waals forces. It seems at present that the only means of characterizing the hydrogen bond in the molecule is the energy required to break it.

The most important and useful method for the discovery of hydrogen bonding is infra-red spectroscopy. The main results obtained up to the present time were discussed by Dr. G. B. B. M. Sutherland. Every molecule containing an *X*H group gives rise to well-marked absorption bands in the near infra-red, which are characteristic of the stretching and contraction of the *X*H bond.

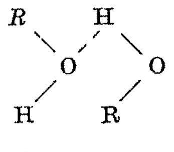
If the hydrogen atom of the *X*H group becomes subject to the influence of a force other than that which binds it to the *X* atom, then the frequency of vibration will be altered and the characteristic band will be shifted. The presence of hydrogen bonds in the molecule can therefore be inferred from the perturbation it produces in the normal *X*H bond. In this way both intermolecular and intramolecular bonds have been determined. As an illustration of the method we may select one of the best-known examples of the hydrogen bond, namely, the dimeric form of the carboxylic acids,



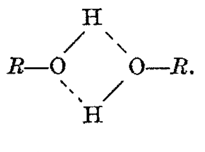
The effect of association is shown by the shift of the OH fundamental frequency at 2·83 μ to 3·25 μ in the acid, and the change in intensity of the band with temperature can be used as a measure of the degree of dissociation of the dimeric molecule, and hence of the heat of dissociation. The method is equally applicable for the study of hydrogen bonds in solids, solutions and liquids. Thus, the association of the alcohols in carbon tetrachloride is characterized by a band at 2·84 μ–2·88 μ, in contrast to the sharp monomeric band at 2·75 μ. Dr. J. J. Fox and Dr. A. E. Martin find that the monomeric O–H bond of benzyl alcohol in carbon tetrachloride has two components, 2·750 μ and 2·765 μ, which seems to indicate two molecular species of the alcohol. At low concentrations this alcohol dimerizes (2·865 μ) and an equilibrium

$$2C_6H_5CH_2OH \rightleftharpoons (C_6H_5CH_2OH)_2$$

is set up, but it is not possible to decide whether the dimer has the structure,

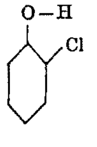


or

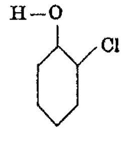


At higher concentrations polymeric association becomes predominant, and this they conclude is in accordance with an equilibrium between dimer and quadruple molecule.

Numerous infra-red investigations have shown the presence of intramolecular hydrogen bonds. The classic example of this group is the two forms of *o*-chlor-phenol,

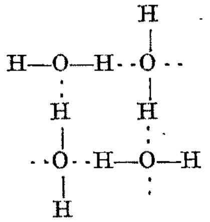


and

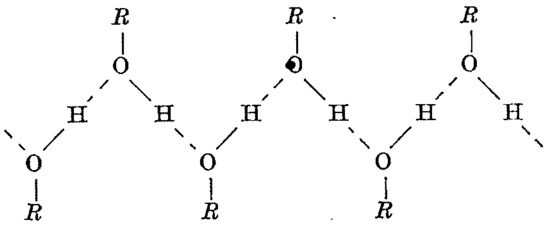


the possibility of *cis-trans* isomerism giving rise to two absorption peaks, one at about 7,050 cm.$^{-1}$ (*trans-* form) and the other at about 6,890 cm.$^{-1}$ (*cis-* form). Many other examples were given in Fox and Martin's paper.

The results obtained by the other powerful method of studying hydrogen bonds was reviewed in a paper by Dr. J. M. Robertson. By this method the distance between the bridged atom or groups forming the hydrogen bond can be directly measured. In this way the presence of hydrogen bonds has been demonstrated in many inorganic and organic structures. Perhaps the most interesting example is that of ice, in which each oxygen is surrounded tetrahedrally by four other oxygen atoms at a distance of 2·76 A. The structure is pictured to be of the type



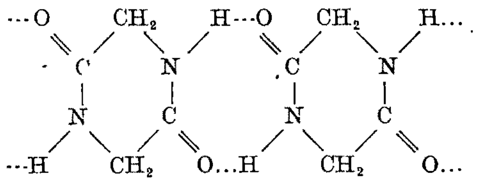
In the crystalline alcohols a similar sort of structure exists, the molecules combining through hydrogen bonds to form indefinitely large structures,



Bernal has suggested that on the basis of results obtained by X-ray analysis, two types of bonds should be distinguished, for which he proposes the names hydrogen and hydroxyl bonds. In the former, hydrogen is attached by equal firmness to two oxygens, O- - -H- - -O, the energy being about 8,000 cal. and the distance between the oxygens being 2·5–2·65 A. In the latter, the hydrogen remains unsymmetrically attached to one of the oxygens, O- - -H—O, giving a bond energy of 5,000 cal. and an oxygen–oxygen distance of 2·7–2·9 A. Since the experimental evidence seems to indicate an almost continuous transition between these two extremes, the necessity for this distinction is not accepted by all.

In a short paper Dr. W. Rogie Angus and W. K. Hill described some preliminary results on a general investigation of diamagnetism and hydrogen bonding. There seems to be every indication that hydrogen bonding should be detectable by susceptibility measurements.

The hydrogen bond may be of great importance biologically, and two papers of the discussion were concerned with the role of hydrogen in determining the structure of the proteins and starch. Our knowledge of the detailed structure of these molecules is still far from complete, and consequently it was not possible to do more than to survey the possible part which hydrogen bonds might take in determining the structure of these substances. In this short summary, one can only restate the conclusion reached by Dr. W. T. Astbury after a critical discussion of the way in which hydrogen bonds may intervene in protein structures, "that whichever way we turn it is impossible to reach a verdict that is really satisfying". However, X-ray analysis of crystalline diketo-piperazine, a substance related to the proteins, shows that the molecules are linked together by hydrogen bonds between their respective oxygen atoms and $=NH$ groups, to form flat continuous chains throughout the structure.



It may be expected that the formation of hydrogen bonds may be important in determining the behaviour of complex molecules containing multiple active hydrogen bond-forming groups, for example, polysaccharides. A critical consideration of this possibility for starch by Prof. E. L. Hirst, Dr. G. T. Young and the present writer shows that the properties of this molecule are inconsistent with those of a structure held together by hydrogen bonds. Analysis of physico-chemical data indicates that the repeating units in starch are held together by normal glucosidic linkages. It is pointed out, however, that the macro-molecules may be associated by hydrogen bonds in native starch.

OBITUARIES

Dr. A. C. Haddon, F.R.S.

On April 10 there passed away in his eighty-fifth year Dr. Alfred Cort Haddon, the doyen of British anthropologists*. Haddon came of Northamptonshire stock, his grandfather founding the firm of John Haddon and Co., printers and typefounders and also produce brokers. The family business connexion brought people from all parts of the world to Haddon's home, and this may well have influenced his choice of a career. From his mother, who wrote children's books, came an interest in natural history, and young Haddon spent much of his time at the Zoo studying and drawing animals. This led friends to advise his father to send him to Cambridge to study zoology, but the boy was destined for his father's business, which he entered on leaving Mill Hill School.

According to Haddon's own account, it took his father scarcely two years to discover that it might be less costly to send his son to Cambridge than to retain him in the firm. So to Cambridge he went, entering Christ's College at the age of twenty, where he worked at zoology under F. M. Balfour and also came under the influence of Michael Foster. It was the former who inspired his first big book, the "Introduction to Embryology" (1887). He took his B.A. in 1879, and was appointed demonstrator in comparative anatomy almost immediately, holding this post until 1880, when he migrated to Dublin as professor of zoology in the Royal College of Science. The M.A. followed in 1882 and the Sc.D. in 1897; he was a fellow of Christ's from 1901 onwards. In 1881 he married Fanny Elizabeth Rose, the sister of his college friend J. Holland Rose (later Harmsworth professor of naval history), by whom he had three children.

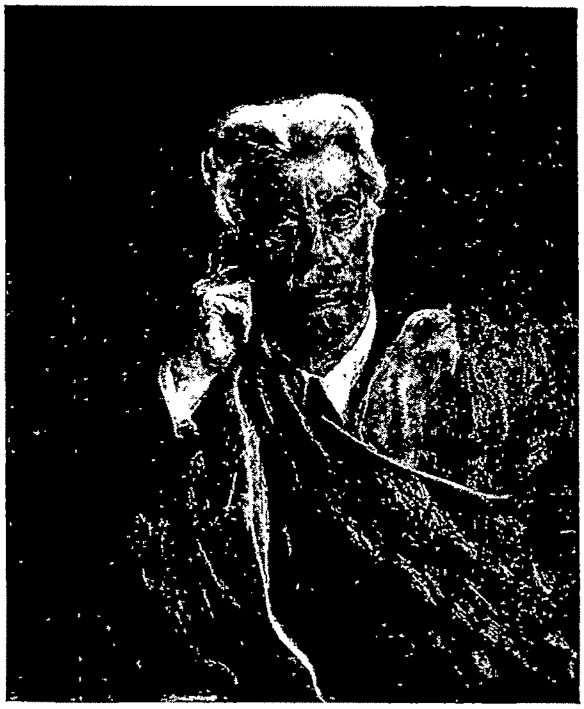
In Dublin, Haddon was active in marine biology, being secretary of the Dredging Committee, which did much work off the south-west coast of Ireland, and this led to a series of papers, mostly on the Actinozoa, in the *Proceedings of the Royal Dublin Society* and the *Royal Irish Academy*. For some years he divided his time between Dublin and Cambridge, lecturing in Dublin during the winter and spending the summers at Cambridge.

So far there is little evidence that Haddon was anything more than a zoologist of recognized ability, and it was in this capacity that he was sent to Torres Straits in 1888, where he spent nearly a year, though an early interest in decorative art (he was then twenty-five) is shown by a letter to NATURE (23, 9–10; 1880) on the Greek fret. The zoological material brought back from this expedition was published in the *Proceedings of the Royal Society* and in the *Transactions of the Royal Dublin Society*. However significant these results may have been, their importance is entirely eclipsed by the alteration that occurred in the man himself, for it was on this first expedition to Torres Straits that Haddon's interest was largely transferred from marine zoology to anthropology. He would relate how, canoeing with the natives and living very much as they did, he became conscious of the change in their old mode of life, that with this came the conviction that it was his duty to save for science what could be saved, whether of their beliefs, language, or arts and crafts. Haddon was, in fact, in time to save most important evidence both of language and of art—witness the splendid collection of turtleshell masks in the British Museum, and the papers written in conjunction with S. H. Ray on the Torres Straits languages.

---

* I wish to thank Miss E. S. Fegan for invaluable assistance in the preparation of this notice.

There was, however, no immediate change of allegiance. When, after his return, Sir William Flower suggested that he should seriously devote himself to anthropology, Haddon, in his own words, "was not very ready to do [so]". There is in existence a most interesting letter written (Nov. 6, 1889) by T. H. Huxley in reply to a request for his advice. "I know of no department of Natural Science more likely to reward a man who goes into it thoroughly than Anthropology. There is an immense deal to be done in the science pure and simple and it is one of those branches of inquiry which brings one into contact with the great problems of humanity in every direction. I once dabbled in it a good deal and I should have liked nothing better than to give myself to it". He goes on to outline the training necessary, and continues: "The only part of your project in which I am afraid to give you any encouragement is the expectation that when the labourer is thus carefully prepared his hire will be forthcoming. I admire Mrs. Haddon's and your pluck immensely, but after all, you know, there is an irreducible minimum of bread and butter, the need of which is patent to a physiologist, if not a morphologist, and I declare with sorrow that—I do not see any way by which a devotee of anthropology is to come at the bread—let alone the butter. And you must recollect (*experto crede*) that the necessity of having to make an income independently of one's proper work—is a frightful burden upon anyone who desires to do that work as it ought to be done. Don't burn your ship in a hurry."



ALFRED CORT HADDON

Reproduction of a portrait by De Laszlo now in the Museum of Archaeology and Ethnology, Cambridge.

Nevertheless, the leaven worked, and Haddon burnt his ship. Finding little scope for his new interests in Dublin, he resigned his professorship within a few years and settled permanently in Cambridge in 1900, having been appointed lecturer in physical anthropology at a salary of £50 per annum the year before. This entailed a considerable financial sacrifice, and he used to allude to this period as one of acute struggle, always emphasizing the encouragement he received from his wife and her constant self-sacrificing assistance.

The idea of revisiting Torres Straits soon crystallized into a definite project, and clearly became an increasing purpose during the next few years. Funds were raised, and on April 22, 1898, the Cambridge Expedition to Torres Straits reached Murray Island, with Haddon as leader. The expedition had from the beginning been planned as something far bigger than a rescue party to a decaying culture, though naturally all possible information bearing on the islanders past and present was collected. It was Haddon who in Great Britain first appreciated the need to study the psychology of 'primitive' peoples, and the importance of that science in relation to what we now call social anthropology. Thus it was that Rivers, McDougall and C. S. Myers became members of the expedition. Here the leader—like so many outstanding men—was ahead of his time; apart from the study of the senses, the psychologists were not yet ready for the anthropologists, nor had more than a limited attention been paid to the unconscious, while the technique of its investigation had scarcely been explored. Nevertheless, this inclusion of psychologists was to lead almost immediately to a most important anthropological development, for it was in the Torres Straits that Rivers elaborated the genealogical method, the most valuable single instrument of investigation that has yet been put into the hands of the social anthropologist. Its importance did not escape Haddon, and in after years he would speak of the conversion of Rivers from psychologist to anthropologist as one of the really important results of the expedition. Haddon did not spend the whole of his time in Torres Straits, but with Ray and Seligman visited New Guinea, where in a few weeks he accumulated an amazing amount of material in every branch of anthropology. On leaving the Straits, he and some other members of the Expedition visited Sarawak, at the invitation of Charles Hose, then Resident of the Baram District.

Election to the fellowship of the Royal Society coincided with Haddon's return in 1899, and from then on his life was so bound up with anthropology as almost to be an epitome of the progress of the science in Great Britain. He was appointed University lecturer in ethnology, becoming reader in 1909 and retaining this post until his retirement in 1926. He was also lecturer in ethnology (Martin White Benefaction) in the University of London during 1904–9. He was president of the Royal Anthropological Institute during 1901–1902, its Huxley Memorial Medallist in 1920, and its first Rivers Medallist in 1924. He was a constant attendant at the meetings of the British Association, presiding over Section H in 1902 (Belfast) and 1905 (South Africa); he was also president of the Folk-lore Society, and of the Cambridge Antiquarian Society. In company with his daughter, now Mrs. Rishbeth, he re-visited Australia and New Guinea in 1914, collecting some fresh material for the "Reports" and greatly increasing his knowledge of Papuasian canoes, knowledge which later led to the publication, with James Hornell, of "Canoes of Oceania".

On his retirement from the Cambridge readership in 1926, he retained his post of honorary curator of the New Guinea collections, which he arranged and catalogued, intending later to do the same for the Borneo material. Leisure from teaching, and intensified contact with museum material, led to the planning of a new work largely concerned with decorative art. This required much museum research —especially in Holland, where he was enthusiastically received—and the MS. of "Smoking and Tobacco Pipes in New Guinea" was completed only a week before his death.

Haddon reviewed for several papers; he was a contributor to NATURE for sixty years, and was the author of countless memoirs and papers, as well as an unusual number of important volumes. This is no place to discuss the Torres Straits "Reports", which he edited and so largely wrote; they speak for themselves. Of his other works, "Iban or Sea Dyak Fabrics and their Patterns" (1936), written in conjunction with L. E. Start, again indicates his persistent interest in decorative art. "Races of Man" (1909, 1924 editions), and "The Wanderings of Peoples" (1911), both illustrate the influence of his zoological training, while the latter book is an exhibition of the extremely condensed style he could at need employ. "We Europeans", written in collaboration with Julian Huxley, is an example of the best form of *œuvre de vulgarization*, produced in the hope of countering some of the insane theories of race now prevailing.

It is surpassingly difficult to give any idea of Haddon the man in a short notice such as this. His strength of build, prominent features, and later his shock of snow-white hair, made him a conspicuous figure in any assembly. Intensely energetic, he had a great capacity for work (in Torres Straits he worked a longer day than any of us), and accuracy of detail seemed to come naturally to him. While the outstanding feature of his character was a broad humanity and kindliness, there was a somewhat unexpected streak of Puritanism, which, however, mellowed greatly as time went on, his wife persuading him to smoke and even to take a drink now and then. He had a keen sense of humour, could be frivolous, and thoroughly enjoyed a holiday as a rest, but in the main his thought and conversation were directed and constructive, and apart from his work he had no hobbies. He was working for an hour or two a day until within a couple of weeks of his death. Far more disinterested than most, there was no one whom he would not go out of his way to help, provided that the claimant was himself doing his best. He hated pretence, and 'side' withered in his presence.

Haddon's work shows a capacity for wide generalizations with, as it seems, a preference for the intensive study of smaller areas in which the intrinsic characters of a people can be compared and contrasted with foreign traits. His method and capacity in this direction are particularly well shown in much of volume 1 (the last written) of the "Reports". It was no doubt his kindliness, tolerance, and honesty of purpose that enabled him to make friends with natives and to gain their confidence in the way he did. "He close up alongside God, he savvy too much" ("too much", that is, a great deal), was the phrase used of him by a Murray Islander, and indeed probably expresses the opinion of all his friends. To have known, appreciated, and been the pupil of A. C. Haddon has been one of my greatest privileges.

C. G. SELIGMAN.

W. R. King

MR. W. R. KING, who died on April 8, aged seventy-two, was Wimshurst's assistant in the development of the Wimshurst electrical 'influence' machine, which of course displaced the frictional machine for the generation of static electricity in the laboratory. This type of apparatus seems to have required quite special skill in the selection and application of apparently simple materials, such as suitable glass and varnishes, necessary for reliability for experiments in static electricity; and Mr. King's experience in this respect was exceptional. The old Nairn machine of Sir Humphry Davy, now standing in the hall of the Royal Institution, owes its restoration to his skill, and he has also carried out similar work for the Science Museum.

In the early days of electrical knowledge numerous and ingenious working models were used to illustrate the behaviour of charged bodies. Many of these were quaint but very striking; Mr. King's collection was unique, and at one of the Friday Evening Exhibitions at the Royal Institution especially, when he showed many of them in action, he easily kept the members interested and delighted to a late hour. He also distinguished himself at the Faraday Exhibition at the Albert Hall in 1931 by a very striking continuous display of lightning from a battery of Leyden jars charged by his largest power machine.

Mr. King's strength had been ebbing for two or three years, continually weakened by bronchial attacks; but he died quietly in his workshop chair. W. J. G.

ROYAL SOCIETY

NEW FOREIGN MEMBERS

M. Le Duc de Broglie

MAURICE, DUC DE BROGLIE, was born in 1875, and has made important contributions to the study of X-rays and the establishment of the now well-known scheme of X-ray electron shells. In 1913, soon after the discovery of the diffraction of X-rays by crystals, he devised a photographic method of investigating X-ray spectra, similar to that developed independently by Moseley in Manchester. During 1920–1922 he used the method of semicircular focusing in a magnetic field to investigate the secondary electrons obtained from these films by the absorption of X-rays. In this way he obtained a direct and beautiful confirmation of the existence of electron energy-levels and of the X-ray quanta. About this time he wrote "Les Rayons X", which was for some years the best account of these phenomena. More recently, the Duc de Broglie has worked on the Brownian movement, on the total reflection of X-rays and on neutron emission. He has served on many committees of the Paris Academy of Sciences, and in 1937 became a member of the Conseil National des Recherches Scientifiques et Industrielles.

Prof. R. G. Harrison

PROF. ROSS GRANVILLE HARRISON, of Yale University, is one of the most distinguished experimental zoologists of to-day. He is probably best known as the originator of tissue culture, his first experiments in this direction being published in 1907. He showed that pieces of the medullary cord of frog embryos could be kept alive in clotted lymph, and he observed the outgrowth of nerve fibres from the explants. Thus he not only originated the method of tissue culture, but also used it, as it should be used, to solve a general problem, namely, that of the mode of origin of nerve fibres. In his later work, he has not by any means confined himself to the tissue culture technique, or even to the problems of the development of the nervous system, important though his contributions to both these fields have been. But, employing grafting methods, he opened up the very important question of the influence of the body of an embryo on the orientation and symmetry of organs grafted into it; and he initiated what is probably the most fundamental approach yet made to the problem of relative growth.

In all these fields, Prof. Harrison's work has been characterized by extreme clarity and precision. His papers are exemplary models, both in contents and presentation, for all young experimental morphologists; and they can be recommended as an antidote to those who think that there can be no exact biology except in those fields within reach of physical and chemical methods; while his Croonian Lecture on the origin and development of the nervous system, given in 1935, is a beautiful example of a broad and penetrating analysis of a biological problem.

Prof. G. N. Lewis

PROF. GILBERT NEWTON LEWIS, of the University of California, is well known for his important experimental researches in electrochemistry. In this field he and his pupils have made some very accurate measurements in difficult fields, including determinations of the electrode potentials of the alkali metals. This work links up with Prof. Lewis's outstanding contributions to thermodynamics, in which he introduced the very original and serviceable conception of the activity. This has been of fundamental importance in the development of the study of strong electrolytes, to which Prof. Lewis and his pupils have made many valuable contributions, and also proved to be very closely connected with the theoretical developments of the subject made by Debye and Hückel.

Another theoretical contribution made by Prof. Lewis was the explanation of covalency as due to electron sharing, and this conception is now firmly established in the modern theory of valency. There are few fields of modern physical chemistry which do not owe something to the highly original and constructive work of Prof. Lewis, and the systematization of thermodynamic data by him and his pupils has also been very important in the application of physical chemistry to industry.

Dr. Francis Peyton Rous

DR. ROUS is a graduate of Johns Hopkins University and has worked at the Rockefeller Institute for Medical Research, New York, since 1909. He is best known for his researches on the problem of transmission of cancer. More than thirty years ago he found a spontaneous sarcoma in a barred Plymouth Rock hen which could be transplanted into other individuals of stock closely related to the fowl in which the growth originally occurred. The fragments of tissue which produced new tumours on injection into other chickens did not contain any visible organisms, and extracts of the ground tumour material produced fresh sarcomata on injection into other fowls even after filtration through apparatus which would retain very small micro-organisms. The tumour, known as the Chicken Tumour I, or the 'Rous sarcoma', retained its distinctive properties whether it was transmitted by a graft of living tissue, by a cell-free filtrate or by dried tumour material, and it is still propagated at the present day. Rous later found many other fowl tumours.

During the last few years Dr. Rous has investigated the Shope rabbit papilloma virus. He has also worked on many physiological problems concerning the liver and blood vessels, the reaction of tissues to injury and vital stains and the preservation of blood. The papers describing the transmissible fowl tumours are classical for accuracy of observations recorded, and for deductions placed on the results.

NEWS AND VIEWS

Imperialism and Service

THE concepts of Empire Day and imperialism were given a new and fuller meaning by H.M. the King in his broadcast address on May 24. He referred in bitter tones to "the spirit of domination and the lust of conquest" to which our enemies give the term imperialism, and he re-defined the term as it now applies to the British Empire. Imperialism, he said, stands for "peace in which our institutions may be developed, the condition of our peoples improved, and the problems of government solved in a spirit of good will". The far-reaching implications of this statement will be readily apparent, and will meet with general approval, for it stamps the British Empire as held together by the strongest but least irksome of bonds, those of friendship and toleration. Of equal significance were His Majesty's words on the consequences of the struggle now in progress. "Defeat will not mean some brief eclipse from which we shall emerge with strength renewed—it will mean destruction of our world as we have known it, and the descent of darkness upon its ruins." All our resources and all our scientific energy are not too much to spend in averting this disaster.

Duddell Medallist of the Physical Society

THE Council of the Physical Society has awarded the seventeenth Duddell Medal to Prof. E. O. Lawrence, of the University of California, Berkeley, for his invention and subsequent development of the cyclotron. Prof. Lawrence, who was born in 1901, went to Berkeley in 1928 and was appointed professor of physics there in 1930. In that year, with M. S. Livingston, he constructed the first cyclotron, which had a comparatively small electromagnet and a pole-gap chamber only six inches in diameter. An 85-ton electromagnet was incorporated in the next cyclotron, designed in collaboration with D. Cooksey; it has an 8-inch pole-gap and a cylindrical chamber 37 inches in diameter. Lawrence was fortunate in obtaining supplies of deuterium oxide from Prof. G. N. Lewis, of the Chemical Department of the University, who had prepared it in quantity. By the summer of 1935, the 37-inch cyclotron had been used to accelerate deuterons to energies equivalent to about 5½ million electron-volts, and 4½ Mev. deuterons had been employed as projectiles for nuclear transformations. Later, 8-Mev. deuterons and 16-Mev. α-particles were produced and used as projectiles to obtain large yields of neutrons from beryllium and also to obtain artificial radioactive elements, for example, 100 millicuries of radio-sodium.

An impressive mass of results has been obtained by Lawrence and his school at Berkeley. Most of them relate to the large number of radioactive isotopes produced by the bombardment of most of the 92 chemical elements with protons, deuterons and α-particles of different energies. Biological effects of neutrons and other products of artificial radioactivity have been studied by Lawrence in collaboration with his brother, Dr. John Lawrence of Yale University Medical School, and wide use has been made of radioactive indicators in the study of metabolism. The new 60-inch cyclotron, with a 220-ton magnet, in the Crocker Radiation Laboratory at Berkeley, has been constructed primarily for biological and clinical purposes, and with it deuterons having energies of about 18 Mev. have been obtained. The Rockefeller Foundation has now undertaken to finance the construction of a 4,900-ton (184-inch) cyclotron, with which it is hoped to accelerate deuterons to energies in the neighbourhood of 100 Mev. With such energies mesotrons may be artificially produced from nuclei.

Prof. F. A. Lindemann, F.R.S.

THE appointment of Prof. F. A. Lindemann as one of the Prime Minister's personal assistants, with particular reference to statistics and research, will be welcomed by scientific workers. Prof. Lindemann, who holds the chair of experimental philosophy in the University of Oxford, has a distinguished record as a man of science and of affairs, going back over the past thirty years. During the War of 1914–18, he was attached to the Royal Air Force and carried out important investigations on spin. Before that time, however, he had done work on the specific heat of solids at low temperatures, and on his appointment to the Oxford chair of experimental philosophy in 1919, he took up investigations on the nature of magnetic storms and on conditions in the upper atmosphere. He has also devised an electrometer now known by his name. Readers of NATURE will recall many contributions in the correspondence columns and elsewhere from Prof. Lindemann and workers in his laboratory. In recent years, Prof. Lindemann has also given much attention to the social consequences of scientific advances. His appointment to a post in close contact with the Prime Minister ensures that the Government will have at hand an adviser who will approach the problems on which he is consulted with full knowledge and appreciation of the scientific method.

Awards of the Institution of Civil Engineers

THE James Alfred Ewing Medal of the Institution, founded in 1936 in memory of the late Sir Alfred Ewing and awarded for specially meritorious contributions to the science of engineering in the field of research, has been awarded for 1939 to Prof. G. I. Taylor, Yarrow research professor of the Royal Society. Prof. Taylor is distinguished for his development of various aspects of mathematical physics, many of which have found applications of great importance in the engineering field. His work on the problem of the turbulent fluid, with special relation to air movements and tides, has furthered knowledge of meteorology, and has been applied to aeronautics, being of material assistance to the fruitful use of the wind-tunnel. He is also a pioneer in the field of research into the conditions in solid bodies during strain, plastic deformation, fatigue, and creep. The practical character of his researches is exemplified by his work on the torsional stiffness of airscrew blades, and he has forged new links between science and engineering to their mutual advantage.

The Sir Charles Parsons Memorial of the Institution, founded in 1936, comprises the erection of a memorial in Westminster Abbey, a Parsons Memorial Library, and an annual lecture on any of the subjects in which Sir Charles Parsons was interested, for which a commemorative bronze medal is awarded. The lecturer for 1939 was Dr. H. L. Guy, who dealt with "Some Researches on Steam Turbine Nozzle Efficiency". Dr. Guy has been the chief engineer of the Mechanical Department, Metropolitan-Vickers Electrical Co., Ltd., since 1919.

Colonial Policy and Scientific Research

NOTWITHSTANDING the preoccupation of Parliament with the grave crisis in the position of the Allies, the second reading of the Colonial Development and Welfare Bill was moved in the Commons on May 21 by Mr. Malcolm MacDonald, Secretary of State for the Colonies in the previous administration. The measure, in spite of an expression from Colonel Wedgwood of his disbelief in the post-War possibility of the financial provision which the Bill proposes, met with the general approval as to its principles from all parts of the House and was read a second time. Mr. MacDonald, in supporting his motion, asked that Parliament, by passing the Bill, should let the world mark our faith in ultimate victory, and our confidence that after the War Great Britain would still exercise vast responsibilities for the Government of colonial peoples. In the subsequent debate Sir George Schuster pointed out that there are no people in the world to whom the success of Germany would be more disastrous than those, for example, in the parts of Africa which we now administer.

That this is no exaggeration may readily be inferred from the Nazi doctrine of the treatment to be meted out to the so-called inferior races. Over against this, Britain may point with justifiable pride to what is unquestionably the most liberal and far-sighted act of policy ever initiated in the history of colonial administration. Not only will the territories under the Colonial Office be relieved of a heavy burden by the remission of £11,000,000 out of their Governments' debt of £15,000,000 to the United Kingdom Exchequer, but also the provision of funds for development and research should ensure that the way to their future prosperity is laid open to them. The provision for research should make it possible to mobilize every resource of science in their service, especially under the leadership of Lord Moyne and Lord Hailey, who, as Mr. MacDonald announced, will act as chairman of the Advisory Committees on Development and Research respectively when these are appointed.

Food and the Housewife

IN a lecture on May 28 at the Royal Institution in the series "The Nation's Larder", Prof. V. H. Mottram pointed out that the housewife who takes an intelligent interest in feeding her family well and according to modern dietetic principles needs some simplified scheme of the facts of dietetics upon which to work. Energy foods are not usually useful for body-building and body-protecting purposes ; body-building foods are often poor as energy and protective foods. Protective foods often have little energy or body-building power. Therefore the foods of one class must not be replaced by those from another class. For example, there is a danger that because we have less meat to eat we may replace it with bread. We must replace it with milk, cheese or fish. Those foods (for example, milk, cheese, fat fish) which combine the functions of two or more classes of foods, are much the most precious foods in diet. The safest rule is first to make sure of the protective foods (dairy foods, greengroceries and the fat fish), add some meat and bacon, and then to satisfy appetite with bread and groceries. Increased consumption of milk, cheese, green vegetables, salad vegetables, fruits and fish such as herrings, sprats, mackerel and salmon (fresh or tinned) is desirable. If this is achieved, it is probable that the energy and even the body-building values of foods will look after themselves. The climate and soil of Great Britain are particularly well adapted to producing protective foods.

Malaria as an Occupational Disease

IN his inaugural thesis (*Thèse de Paris*, No. 707 ; 1939) Dr. J. C. Lévy states that malaria is regarded as an occupational disease, for which appropriate compensation should be made, in certain countries, particularly North America (especially the States of Wisconsin and Illinois), Brazil, Spain and Italy, where its frequency as an occupational disease has given rise to special legislation. In France, on the other hand, there are no legislative measures recognizing malaria as an occupational disease, and compensation for contracting it is allowed only in the case of soldiers, sailors and airmen. Dr. Lévy therefore demands that malaria should be added to the list of occupational diseases in France for the following reasons : first, to repair the material damage to which a variety of workers are liable, namely, colonials and labourers in the veldt or canals, and secondly, for the adoption of additional prophylactic measures in conditions and localities where the work involves the risk of contracting malaria.

The Nature of Virus

DR. THOMAS M. RIVERS discussed the possibilities that viruses represent a transition between living and non-living matter, at a meeting of the New York Academy of Medicine on March 29. A report of the meeting issued by Science Service mentions that the discovery of bacteria was formerly held by some men of science to indicate the origin of life in the world. Many workers now believe this to be the case for viruses. Dr. Rivers discussed the retrograde and the evolutionary vital theories, and also the non-vital autocatalytic ideas of several students of the problem. He pointed out that the weakness of these conceptions is that viruses may not all be similar, and such a plastic group may well embrace all the forms mentioned.

Venereal Disease in the United States

THE United States Public Health Service reports that treatment and laboratory facilities and services in the control of venereal disease increased between 30 and 85 per cent during the last fiscal year ending June 30, 1939. Every State Department now has a separate division or sub-division for the control of venereal disease. Approximately 103,000 persons were discharged from clinics as cured or the disease arrested in 1939, as compared with 78,000 in the previous year. Persons treated for the first time numbered 305,000 and the number of treatments administered was 8,000,000. Training centres for physicians and nurses in venereal disease control have been established in nine universities.

Earthquakes in Peru

AN earthquake on the night of May 24 did considerable damage to the towns of Lima and Callao in Peru. A dry dock and pier at Callao were damaged, part of a building belonging to the College of St. Thomas Aquinas collapsed, and hundreds of other buildings were destroyed. Two aftershocks of some severity followed on May 25. As a result of the shocks it is estimated that there were 300 dead and 1,500 injured in the two towns, though detailed information is lacking owing to the temporary severing of communications with the area as a result of the earthquakes. Although the whole of Peru is subject to minor earthquakes and earth tremors, the present epicentre appears to be farther north than the most seismic district in Peru, namely, the regions around Arequipa. On January 8, 1725, an earthquake with its epicentre near Arequipa caused widespread destruction and damage was caused in Lima. In the present instance no news has yet been heard of Arequipa. Slight tremors, possibly sympathetic with the above, have also been felt at Guayaquil in Equador.

Agricultural Work for University Students

A SCHEME has been prepared by the Ministry of Agriculture and Fisheries to encourage students at universities and colleges to undertake agricultural work during the summer vacation. Recruiting bureaux have been set up at the principal universities, where full particulars of the scheme and application forms may be obtained. Volunteers will receive at least the appropriate minimum wage-rates fixed by the local agricultural wages committee. This particular scheme is intended for men only, but the Minister also appeals to women students who are willing to spend four weeks or more on the land to join the Women's Land Army Auxiliary Force, particulars of which may be obtained from the local county secretary of the Women's Land Army, or from the headquarters at Balcombe Place, Balcombe, Sussex.

The Parliamentary and Scientific Committee

AT a meeting of the Parliamentary and Scientific Committee at the House of Commons on May 22 it was decided in view of the grave situation to hold regular weekly meetings in future to examine all ways by which a greater application of scientific knowledge could be applied to the conduct of the War in its various aspects and to bring these matters to the immediate notice of the appropriate Ministers. The first of these meetings was held at the House of Commons on May 29.

Announcements

AT the anniversary meeting of the Linnean Society of London held on May 24 the following were elected officers for the year 1940–41 : *President*, Dr. E. S. Russell ; *Treasurer*, Mr. Francis Druce ; *Secretaries*, Mr. I. Henry Burkill (botany), and Dr. Malcolm Smith (zoology). The new members of the Council are Mr. J. S. L. Gilmour, Mr. J. R. Norman, Dr. C. F. A. Pantin, Dr. E. S. Russell and Major F. C. Stern.

SPECIMENS of a rare nickel-iron sulphide mineral, bravoite from Mill Close Mine, Derbyshire, have been presented to the Department of Mineralogy of the British Museum (Natural History) by Prof. W. G. Fearnsides. This is the first known occurrence of the mineral in the British Isles.

THE attainment of the Government's ploughing-up objective in Great Britain and Northern Ireland was announced on May 23 in the House of Commons by the Minister of Agriculture and Fisheries. The total additional grassland ploughed amounts in England and Wales to 1,542,236 acres—an excess of 42,000 acres over the target programme of 1½ million acres. When the figures for Scotland (about 222,000 acres) and Northern Ireland (about 270,000 acres) are added, a grand total of 2,034,236 acres is obtained.

THE Association for Education in Citizenship is organizing a Summer School at Lady Margaret Hall, Oxford, during August 7–14, the subject for discussion being "Education for Effective Democracy". Further information can be obtained from the Association for Education in Citizenship, 10 Victoria Street, London, S.W.1.

THE Brighton Summer School in Animal Biology will be held during August 3–15 at the Municipal Technical College, Brighton, under the direction of Prof. L. E. S. Eastham. Further information can be obtained from Mr. F. H. Toyne, Education Officer, 54 Old Steine, Brighton.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 863. CORRESPONDENTS ARE INVITED TO ATTACH SIMILAR SUMMARIES TO THEIR COMMUNICATIONS.

The Universities and Research

THE leading article in NATURE of April 27 opened with a paragraph which purported to give the reasons for university authorities encouraging their staffs and students to do research work : ". . . the *principal* reason, especially applicable to the students, probably being that research is excellent educational training and therefore falls within the sphere of the primary activity of universities. A *secondary* reason, especially applicable to the staffs, is that research may produce results of great *public* benefit and is, *to that extent, not inconsistent with* the reason for existence of universities" (italics mine).

It may be that the writer (whose main concern in this article was with patentable discoveries) had to express himself in this introduction with a hard-and-fast conciseness which has misled me, and which he might have wished to elucidate if he had had more space. But I will own that his words quoted above, especially those which I have italicized, stirred in me a feeling of dissent, akin to that roused in many of us who live and have our being in universities by certain publicists (and even by writers in NATURE) who of late years have attempted to gauge and guide our work by standards which we feel are faulty. The passage seems to ascribe to "university authorities" grudging and illiberal ideas about academic research which, to my knowledge, many of them do not hold. Others of them would, I believe, consider that the statement begs large questions, and they would not be ready to endorse it without changing at least the balance of its emphasis. Some—but, I think, very few—might give it a casual and more or less cynical assent. On the other hand, many people whose working life does not make them "university authorities", and whose view of our universities is limited or external (with, usually, some background of former studentship in one of them), would subscribe to the statement. If the following different statement puts little that has not been said before (and criticized) about academic research and university authority, perhaps I may preface my own excursus on these two matters by borrowing, in a modest way, the classic retort of some advocate of honesty as the best policy—"I have tried both".

In normal times, and where thought and speech are free to all who can think and speak, spontaneous inquiry must be free to all who can inquire. The primary activity of a British university is the cultivation of informed inquiry and the development of its techniques. The training stages of this—by which stages I mean all undergraduate curricula and the postgraduate studies—must go on inseparably within the same walls as a maturer use of the diverse and changing techniques if either sort is to be kept alive. Without that continued and equal coupling, universities cannot do their teaching duty to the ordinary undergraduate, or their duty (inherent in no other system of institutions) as the nurseries both of new knowledge and of the men to make it.

As to the public benefit of such new knowledge : a university may sometimes find it easier to get from non-academic sources money for researches which have an immediate and obvious public use, than to get it from them for other inquiries. This is, however, not usually the case; for as a rule the former kinds of research are the more expensive, and there are also alternative homes for them. But, as need scarcely be said, immediate public utility is not the standard by which university authorities measure the value of university researches ; nor by that scale do they mete out such encouragement as they are privileged to give to true investigators, whether these are scientific, or technological, or work in the domains of letters and scholarship.

In time of peace to insist, as various people have tried to do of late years, that the active curiosities of original minds shall be turned aside to topics selected by non-practitioners or lay arbiters as bearing on current public problems ; to constrain into 'practical' themes men of highly specific abilities, whose reason for living hard and (by newspaper standards) inconspicuous lives is that they crave to know certain sorts of unknown things and can endure the long process of finding out : all this is a kind of regimentation which would frustrate its own ends. For the mind of the genuine researcher (as distinct from imitations, here negligible) simply will not work productively upon things in which it is not technically interested, or on 'problems of the day' which he knows are too crowded with shifting and arbitrary variables to be resolved by means of his specific aptitudes. Each researcher is a key that opens only the range of locks which it fits. His own results are normally what the public calls 'useless', because they are beyond the horizon of even the educated contemporary layman, and because the integrated effects of them and their like will not reach the surface of public apprehension for a long time to come. That future time would be intellectually sterile, *its* educated laymen atavisms instead of our heirs, but for present-day 'academic' work, wherein the investigator follows the inspirations of his own instructed nose, and not the noses of those who plunge about after more noticeable scents.

If these views are called reactionary, I do not much care, so long as I am not thought by implication to decry the doing of applied research by all who can do it well. (Invention is another matter.) But I myself think those people reactionary who have lately been preaching that academic scientists are unsocial irresponsibles, wreaking they know not what in a world which they ignore, and that their talents should be turned upon public affairs. That is an old and seductive song; its dwindling had been an improvement, its renewal in time of peace was a backward and a timorous move. In war, of course, the deflection of research ability to short-focus utilitarian questions is necessary; and it is valuable to the nation in measure as the specific aptitude and the common sense of each worker are properly noted in allotting him his war task. Afterwards, he will return again, if he can, to his work as an active philosopher; and no doubt he will yet again be grudged the exercise of that function—but not by university authorities.

J. I. O. MASSON.

The University,
Sheffield.
April 30.

Vitamin B_1 and Acetylcholine Formation in Isolated Brain

WE have shown in earlier papers[1] that in the presence of glucose or of pyruvate and under aerobic conditions brain tissue, whether sliced or minced, synthesizes acetylcholine. In the absence of such substrates, little or no synthesis takes place. Since it is well known from the work of Peters and his colleagues that the presence of vitamin B_1 (as cocarboxylase) is necessary for the oxidation of pyruvic acid in brain *in vitro*, it becomes of interest to discover whether the presence of vitamin B_1 has any influence on the rate of acetylcholine synthesis in isolated brain tissue. MacIntosh[2] investigated the acetylcholine contents of brains of polyneuritic pigeons and found these to be of the same order as those in the brains of normal pigeons. We have examined the abilities of intact brain slices, from normal and polyneuritic pigeons, to synthesize acetylcholine under suitable aerobic conditions in bicarbonate – Locke – pyruvate media containing eserine. (The eserine is added to prevent the decomposition of the acetylcholine by the choline esterase in the tissue.) We have found no appreciable difference between the rates of acetylcholine formation in normal or polyneuritic brain tissue examined under these conditions; nor have we found as a general rule that the addition of vitamin B_1 has any significant effect upon these rates. (On one occasion we found that the addition of vitamin B_1 definitely increased the rate of acetylcholine formation by polyneuritic pigeon brain in a phosphate–pyruvate medium.)

Quite a different result, however, is obtained if the brain slices are examined aerobically in a bicarbonate – Locke – pyruvate – eserine medium containing a relatively high concentration (0·03 *M.*) of potassium ions. Under these conditions polyneuritic pigeon brain synthesizes acetylcholine at a smaller rate than in the case of normal brain. The addition of vitamin B_1 to the polyneuritic brain restores the rate of acetylcholine formation to the normal. The addition of vitamin B_1 to the normal pigeon brain, on the other hand, has no significant effect on the rate of acetylcholine formation. Typical results are shown in the accompanying table, where total acetylcholine was estimated by the technique described in our papers.

PIGEON BRAIN SLICES IN BICARBONATE (0·025 *M.*)—LOCKE–ESERINE (1/6,000)–PYRUVATE (0·01 *M.*) MEDIA. INCUBATED FOR 1½ HOURS AT 37° IN AN ATMOSPHERE OF 95 PER CENT OXYGEN + 5 PER CENT CARBON DIOXIDE

	Condition of pigeon	K+ concentration added to that in basal medium	Amount of vitamin B_1 added	Total acetylcholine Cl formed. γ/gm. wet weight of brain tissue
Expt. 1	Normal	Nil	Nil	9·8
	,,	Nil	4 γ	9·6
	,,	0·03 *M.*	Nil	27·0
	,,	0·03 *M.*	4 γ	24·8

Expt. 6	Polyneuritic	0·03 *M.*	Nil	15·2
	,,	0·03 *M.*	4 γ	23·4

To explain this phenomenon (see ref. 1), it is important to point out that the total acetylcholine, measurements of which are given in the accompanying table, is made up of the sum of bound and free acetylcholine. The quantity of bound acetylcholine which is formed cannot exceed a certain value, this being determined by the amount in the cell of a (? protein) component which enters into the constitution of the bound acetylcholine. Free acetylcholine arises by breakdown of the bound ester, and the amount of free acetylcholine is determined by the rate at which the bound form breaks down to produce the free ester. An equilibrium exists in the cell between the concentrations of bound and free esters. Normally the rate of formation of bound acetylcholine is much faster than the rate of liberation of free acetylcholine, but, as stated before, not more than a limited quantity of the bound ester can be synthesized. It is therefore understandable that a diminution in the rate of synthesis of the bound ester may take place without affecting the final quantity, or the limiting concentration, of bound acetylcholine in the cell. Hence the rate of formation of total acetylcholine may be independent of small changes of the rate of synthesis of the bound ester. In the presence of relatively high concentrations of potassium ions, however, the rate of formation of free acetylcholine is greatly increased, presumably by an increased rate of diffusion through the cell wall[1]. In this case a relatively small fall in the rate of synthesis of the bound ester may be such as to prevent the attainment of the limiting concentration of the bound acetylcholine, owing to the increased rapidity with which the latter is being broken down. Under such conditions the rate of synthesis of bound acetylcholine determines the rate of formation of total acetylcholine. It is in these circumstances that we may hope to see pronounced effects, on the rate of acetylcholine formation, of changes of pyruvate metabolism in the brain caused by variations of vitamin B_1 content.

The experiments the results of which are recorded in the accompanying table show clearly that the presence of vitamin B_1 affects the synthesis of acetylcholine by polyneuritic brain in the presence of pyruvate. In the absence of substrate we have observed no accelerating action due to the action of vitamin B_1. Hence the action of vitamin B_1 on acetylcholine synthesis is linked with pyruvate metabolism. It is, however, uncertain whether the effect of the vitamin is to be attributed to its influence on pyruvate oxidation or upon some other phase of pyruvate metabolism in the nervous system.

Amino-Acids of Casein Phosphopeptone

THE proof of any hypothesis of protein structure must in the last resort be based upon the isolation of partial cleavage products of definite composition, ranging in complexity from the amino-acid to the intact protein, and the elucidation of their constitution. From this point of view the phosphorus complexes formed from casein by enzymic digestion provide attractive material for investigation, as the phosphorus serves as a helpful label for isolation identification.

Rimington[1] isolated a trypsin-resistant phosphopeptone from casein which he claimed was made up of 3 mol. of hydroxyglutamic acid, 4 mol. of hydroxyaminobutyric acid and 2 mol. of serine. However, on several grounds, the problem appeared to require re-investigation. In particular it may be mentioned that Harington[2] has been unable to identify hydroxyglutamic acid as a constituent of casein.

By digesting with trypsin the precipitate of 'paranuclein' (obtained by the action of pepsin on casein, and containing about 50 per cent of the total phosphorus of the protein), a phosphopeptone of constant composition resistant to the further action of trypsin is formed. The substance, isolated as the barium salt which is insoluble in 50 per cent alcohol, has an amino-N content of 10 per cent and a N : P ratio of 3·2 to 3·3, indicating a polypeptide made of 10 amino-acids united to three phosphoric acid residues. Analysis of the products of hydrolysis carried out on many separate samples shows the amino-acid composition to be: 3 mol. of glutamic acid, 3 mol. of *iso*leucine, and 4 mol. of serine.

The glutamic acid was isolated either as the hydrochloride or by precipitation with barium hydroxide and alcohol according to the modified Foreman method[3], the yields being 29·7 and 28 per cent respectively of the total nitrogen. The yield of *iso*leucine (separated by means of butyl alcohol extraction[4] followed by conversion to copper salts[5]) was 27·9 per cent. For the separation of serine, fractional crystallization was the only serviceable method and the best yields came to only 13·1 per cent of the total nitrogen. However, by oxidation of the hydrolysate with chloramine-*T* and gravimetric determination of the glycollic aldehyde formed as the 2 : 4-dinitrophenylosazone the serine present was also found to account for 28·9 per cent of the total nitrogen of the phosphopeptone. 10·9 per cent of the total nitrogen was present in the hydrolysate as ammonia. From the time course of ammonia liberation in the presence of dilute acids[6] it has to be concluded that the ammonia arises not from an amide group but from secondary decomposition, most probably of serine. This is supported by the fact that glyceric acid can be isolated from ether extracts of the hydrolysate in the form of its quinine salt. Small amounts of pyruvic and lactic acids also appear to be formed. The absence of any hydroxyamino-acid other than serine has been established by oxidation of the various fractions by means of chloramine-*T* and the identification of the osazones formed with phenyl, *p*-nitrophenyl, and 2 : 4-dinitrophenyl hydrazine. Only glyoxal osazone was formed.

Certain difficulties in the analytical procedure caused by the presence of serine are worth special mention, as they are of general significance in protein analysis and also throw some light on the alleged isolation of hydroxyglutamic acid. Under the usual conditions of precipitation of the dicarboxylic acids by barium or calcium hydroxide and alcohol, serine is also precipitated to a considerable extent. Glyceric and pyruvic acids formed by the secondary decomposition of serine are similarly precipitated; these acids interfere further in the estimation of dicarboxylic acids by titration also. In distinguishing the hydroxyamino-acids by oxidation with chloramine-*T* it has to be remembered that the melting points of the *p*-nitrophenylosazones are not suited for identification; the phenylosazones are more serviceable.

Full experimental details will be published elsewhere. The question of the order in which the amino-acids are present in the phosphopeptone is being now investigated.

Cancer Cell and Growth-Regulating System of the Body

A FRAGMENT of tissue removed from the body and explanted *in vitro* does not commence growing immediately. A certain period of time must elapse before proliferation sets in. In a paper some years ago which has been overlooked in the literature on tissue culture, Cohn and Murray[1] reported that the period between the moment that the tissue fragment is explanted *in vitro* and the first appearance of new cells varies with the age of the embryo. As the embryo develops, this latent period becomes progressively longer. The latent period of adult tissue explanted *in vitro* is considerable as compared to that of embryonic tissue. We have demonstrated[2] that it is approximately three times longer than that of tissue taken from an embryo in a late developmental stage. Furthermore, we have shown that during postnatal growth the latent period increases gradually[3]. It reaches its maximum when the animal ceases growing and remains constant thereafter, not even changing during senescence[3,4].

The fact that after explantation a definite period must expire before proliferation sets in may be explained by assuming that the growth-inhibiting factors which act in the organism remain active for a certain length of time outside the body. The progressive increase of the latent period, corresponding to the successive developmental stages of the growing animal in embryonic and post-natal periods, could then be due to an increase in the forces which oppose cell multiplication in the organism. This explanation of the significance of the latent period and its variations is based on the hypothesis that tissue stability in the body is a result of the balance between the growth-proliferating and -inhibiting mechanism (Murphy[5]).

In the light of the above conception, we thought it important to investigate the latent period of neoplastic tissue explanted *in vitro*. The experiments here reported were carried out with explants from benzpyrene sarcoma of rats and Rous sarcoma of chickens. The tumour fragments were planted in Carrel flasks containing plasma diluted with double its volume of Tyrode solution and one drop of dilute embryonic extract. The flasks were kept in the incubator at 37° C. and examined at regular intervals. The time was noted when the first cells appeared on the margin of the explanted fragment.

A total of 490 explants from 14 tumours (9 rat sarcoma and 5 Rous chicken sarcoma) were used in these experiments. All the explanted fragments commenced to proliferate *in vitro* following a latent period which was very much shorter than that of normal adult tissue. Whereas in normal adult tissue the latent period ranges from 18 to 28 hours, in neoplastic tissue it never exceeded 8 hours. Moreover, it must be emphasized that in about half of the experiments the first cells appeared on the margin of the tumour fragments after 40–50 minutes—that is to say, practically without any latency. This absence of a latent period places tumour tissue in a unique position compared with all other tissues, normal adult as well as embryonic tissue. Even early embryonic tissue, taken from 6–7 day old embryos, always has a latent period of between 1½ and 4 hours.

The fact that explants of tumour tissue begin to grow *in vitro* after a very short, or even without any, latent period affords evidence of the unique position of tumour tissue with regard to the growth-inhibiting mechanism of the organism. We see herein experimental proof for the conception, increasingly gaining favour, that "what distinguishes a malignant cell from a normal cell is its freedom from control by the organism to which the normal cell is subjected" (Cramer[6]).

A detailed report will be published elsewhere.

Serological Properties of Extracts of Hæmolytic Streptococci prepared by Ultrasonic Vibrations

IT has been shown[1] that in order to produce protective sera of high potency against hæmolytic streptococci the vaccines employed for immunization have to be prepared from cocci cultivated for a few hours only. While such young cocci are well capsulated, the capsules are lost after the early stage of growth. The assumption seemed therefore justified that an antigen contained in the capsular substance is responsible for the production of protective antibody. Since it is also known[1] that this antigen is highly labile and easily altered by chemicals or excessive heat, in any attempt at its isolation a method must be used which interferes as little as possible with the constitution of the antigen. Disintegration of streptococci by sonic vibrations of audible frequency has previously been described by Chambers and Flosdorf[2], and Mudd and collaborators[3,4] have used this method for the extraction of labile antigen. The results of these workers have, however, no direct bearing on the problem of the streptococcal capsule as they employed 'overnight' cultures only in their investigations. It was thought that disintegration of the cocci by means of ultrasonic vibrations would liberate the antigen unaltered.

This expectation was tested in the following manner. A suspension of the streptococci was hermetically sealed in thin-walled glass test-tubes and held in an oil bath containing a powerful quartz piezo-electric oscillator operating at 550 kilocycles per second. The ultrasonic generator has already been described and is the same as that employed by Hopwood and Gordon[5] and by Hopwood, Salaman and McFarlane[6] in their experiments on vaccinia virus.

Preliminary experiments were undertaken to find out how long the streptococci had to be exposed to the vibrations under the experimental conditions in order to be deprived of their capsules. This time was found to be about four minutes when 5 c.c. of a suspension of streptococci in saline made up from the sediment of 100 c.c. of a 2 hours-culture was used. For the main experiments six minutes was chosen as the time of exposure.

The periods of irradiation were always interrupted to permit the cooling of the suspensions in a bath of ice water, and so prevent any undesirable rise of temperature.

After the exposure the suspension of streptococci was centrifuged and the supernatant portion filtered through Berkefeld V candles. Immune sera precipitated these crude extracts prepared from young as well as from overnight cultures, but an extract prepared from a well-capsulated young culture was still precipitated by the homologous immune serum after absorption with the sediment of an overnight culture. A similar quantity of young cocci completely exhausted the serological activity of the serum. Attempts to isolate and purify the type-specific antigen from extracts prepared from young and overnight cultures respectively also showed that the amount of type-specific antigen present in ultrasonic extracts was larger when these were prepared from young cultures. The type-specific antigen of Group *A* hæmolytic streptococci having the characteristics of a nucleo-protein is precipitated by weak solutions of acetic acid. In the case of a Type 3 streptococcus in the non-mucoid phase, precipitation of ultrasonic extracts with acetic acid yielded serologically active material only when the extracts were prepared from young cocci. With streptococci of Types 3 and 13 in the mucoid phase, however, the first precipitation with acetic acid yielded active material from extracts both of young and overnight cultures. Further purification led finally to fractions where serologically active substance was demonstrable only in those derived from young cultures.

The result of these experiments is in favour of the assumption that fully capsulated young cultures of hæmolytic streptococci provide a better antigen than overnight cultures owing to their larger content of unaltered type-specific antigen. However, since the disintegration of streptococci by ultrasonic vibrations liberates serologically active material not only from the fully capsulated cocci, but also from those possessing no demonstrable capsule, these observations, though very suggestive, cannot be taken as conclusive proof that the type-specific antigen of streptococci is situated only in the capsule.

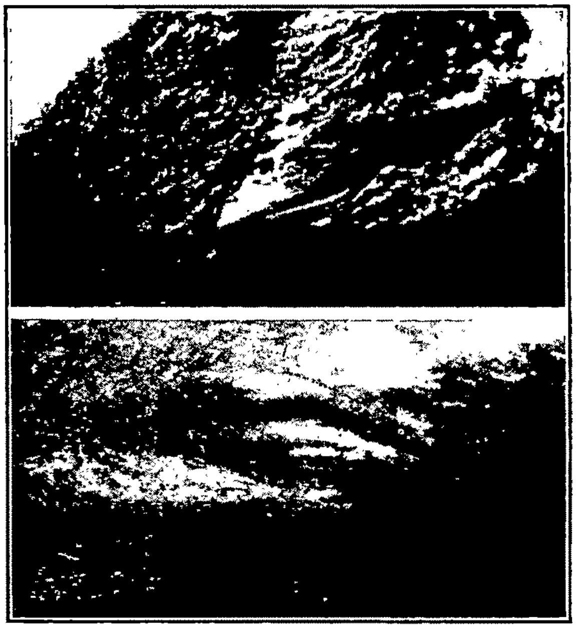
Upper Canine Teeth in the Indian Antelope (*Antilope cervicapra*)

UPPER canine teeth do not persist in either sex throughout the Bovidæ, but the occurrence of these teeth even in young animals at any stage of development has seldom been recorded. Regarding the antelopes, Forsyth Major in 1904[1] stated that "deciduous upper canines have not often been recorded. . . . I can find only five writers who mention them". He himself added notes upon their presence in five species, mostly in very young or fœtal individuals, and came to the conclusion "that calcified rudimentary milk-canines will be found to be normally present in all fœtal and most very young Antelopes, and that it is owing to the scarcity of fœtal and very young skulls in our Museums that they have not been observed more frequently" (p. 422).

At various times I have received from the Park of the Zoological Society of Scotland the bodies of three Indian antelopes or black buck (*Antilope cervicapra*) which have died at or within a few days of birth. In one individual (1937. 15. 21), three days old, rudimentary upper canines were present, but were lost during the process of macerating the skull; in a second (1937. 15. 2), which died just after birth, well-formed and definitely edged open alveoli are present, and although no teeth were seen the alveoli indicate that rudiments must have existed. In the prepared skull of the third specimen (1940. 8), one day old, no alveolus was visible, but dissection revealed the presence in each jaw of a rudimentary canine, 4 mm. long, lying almost parallel to the free edge of the maxilla, and showing in median section a large pulp cavity (see accompanying figure). There is only one record of the presence of rudimentary upper canines in the Indian antelope, by Nehring[2], who, in parenthesis, remarks that in the upper jaw prepared by him from a young individual which died in a zoological garden, two well-developed canine teeth were present.



DISSECTIONS SHOWING RUDIMENTARY UPPER CANINE TEETH OF THE INDIAN ANTELOPE (× 7·5). ABOVE, LEFT JAW, TOOTH IN MEDIAN SECTION: BELOW, RIGHT JAW, SAME SKULL, EXTERNAL ASPECT OF TOOTH.

The result of the examination of three additional skulls of the Indian antelope suggests that in that species rudimentary upper canines may be present in all fœtal individuals, although they do not cut the gum and may scarcely reach the level of the surface of the maxilla. This evidence supports Major's belief that rudimentary canines will be found in all fœtal or very young antelopes. On the other hand, Lönnberg[3] has examined eight very young skulls of different species in the collections of the Natural History Museum at Stockholm without observing "a single indication of upper canines or traces of alveoles after such". It is possible, however, that even in these cases dissection would have shown the presence of rudimentary canines. Lönnberg describes moderately well-developed upper canines in a young skull of *Gazella granti* from East Africa.

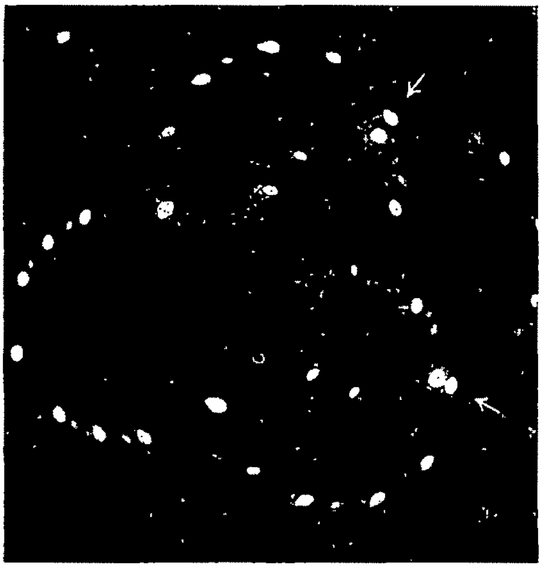
Reflection of X-rays with a Change of Frequency

A change of frequency in the scattering of light or of X-rays is a familiar phenomenon. On the other hand, the coherent X-ray reflections given by crystals are a consequence of classical optics and any change of frequency in such reflection might seem inadmissible. A closer consideration shows, however, that even on the classical theory, a change of frequency might accompany a coherent reflection, if the structure-amplitude of the crystal planes responsible for the reflection were to vary periodically with time. This would occur, for example, when the interpenetrating lattices in the crystal oscillate against each other with the characteristic infra-red frequencies and produce pulsations of the electron-density in the crystal. On the principles of the quantum theory, therefore, such lattice oscillations, though initially non-existent, may be excited as the result of the incident radiation and give rise to a *coherent reflection of altered frequency*.



Laue Pattern of Sodium Nitrate.

Consider the effect on a beam of monochromatic X-radiation passing through a crystal of a set of spacings having a large structure-amplitude. If the angle of incidence on these spacings is different from that given by the Bragg formula, the usual type of X-ray reflection would be forbidden. A periodic variation with time of the structure-amplitude, *if it has the same phase throughout the crystal*, would also fail to give rise to a reflection with modified frequency. In other words, reflections with and without modification of frequency would occur only in accompaniment with each other. On the other hand, if the variation of structure-amplitude has not the same phase everywhere, the two types of reflection may occur independently. While the unmodified reflections could appear only at the correct Bragg angle of incidence on the crystal spacings, the modified reflections would not be restricted to such incidences. The direction in which they appear would correspond with that of geometric reflection, *not from the crystal spacings*, but from the plane waves of constant phase of the structure-amplitude variations. The inclination of these waves would, in fact, be uniquely determined by the circumstances of each reflection, as these must satisfy the Bragg condition as well. In other words, on the quantum theory, only that particular mode of oscillation would be excited which would give the observed reflection.

A crystal of sodium nitrate gives excellent examples of these modified reflections. The accompanying illustration is a Laue pattern obtained with such a crystal, the direction of the incident X-ray pencil (from a copper target) being normal to one of the three pairs of the rhombohedral cleavage faces and therefore equally inclined to the other two pairs of such faces. Along the two radial lines marked in the figure will be seen following each other in order, the usual Laue reflection from the cleavage spacings and the modified reflections corresponding to the incident copper K_α and copper K_β monochromatic radiations. Still nearer the centre will be seen the faint radial streaks corresponding to the modified reflections of the incident white radiations.

Fission of Uranium and Thorium under Deuteron Bombardment

In continuation of the experiments on uranium fission under deuteron bombardment reported by Gant[1] from this laboratory, we have carried out a chemical separation of the recoil products. The particles projected from the uranium target under deuteron bombardment were collected on an aluminium foil using the experimental arrangement described by Gant. The foil was then dissolved in aqua regia and, after adding the necessary carriers, platinum, barium and lanthanum separations were made in the usual way. The activities observed were 15 min., 1 hr. and 30–40 hr. with the platinum fraction, 11 min. and 80 min. with the barium fraction, and 4 hr. with the lanthanum fraction. Some of the periods are thus found to correspond to those obtained with neutron fission in uranium[2], in agreement with Gant's conclusion that 9 Mev. deuterons are capable of producing fission in uranium. Control experiments with lead and bismuth targets failed to show any appreciable activities in the carriers.

Using the same experimental arrangement as before, we have bombarded thorium with 9 Mev. deuterons, a thin layer of metallic thorium being used as the target. Seven minutes after a $6\,\mu$ amp. min. bombardment, an aluminium foil F (3·3 mgm./cm.^{2}), which had been placed inside the side pocket of the target box and protected from the low-energy products due to mechanical disintegration of the target by 2 mm. S.P. aluminium, gave an activity of about 1,200 counts per min., whereas a second aluminium foil D which was placed behind the foil F and therefore measured the scattered deuteron effect, gave an activity of 100 counts per min., decaying with the well-known 2·4 min. period of ^{28}Al. The activity produced in a third aluminium foil N, placed inside the pocket but separated from the foil D by a copper sheet (½ mm. thick), was of the order of 20 counts per min. The activity of *F* was found to decay with a composite period, the decay curve agreeing with that calculated from Frisch's formula[3]. With a target entirely of lead, *F* as well as *D* showed only a small effect. Replacement of the aluminium foil as a collector of fission products by pieces of ciné film did not appreciably affect the activity of *F*.

The magnitude of the fission effect caused by the background neutron radiation produced at the target was assessed by measuring the neutron-induced fission in a second thorium target enclosed in the side pocket and safely protected from the scattered deuterons. After identical bombardments, the activity on an aluminium collector placed in front of the second thorium target and separated from it by aluminium of 2 mm. S.P. was less than one thirtieth of that observed in the case of direct deuteron bombardment.

The maximum range of the radioactive nuclei projected from the thorium target under 9 Mev. deuteron bombardment was found to be equivalent to about 1·8 cm. of air. Excitation function measurements showed that the threshold for deuteron fission of thorium is at about 7·5 Mev. and that the fission cross-section increases rapidly between 8 and 9 Mev.

Chemical separation of the deuteron-induced fission products of thorium gave the following periods: platinum fraction, 18 min. and 2½ hr.; barium fraction, 15 min.; and lanthanum fraction, 2·5 hr.

Comparison between the fission cross-sections of uranium and thorium for 9 Mev. deuterons showed that for thorium the cross-section was about two thirds of that for uranium.

We wish to express our gratitude to Mr. D. H. T. Gant for lending us his apparatus and also for valuable suggestions.

Change of Ultra-Violet Transparency of Glass with Temperature

The transmission of ultra-violet light by glass in the region of 3000 A. has long been known to be reduced when the glass is exposed to light, and restored by heating to 250–300° C. Slow restoration also takes place when the glass is kept in the dark.

Another effect has been examined, not to be confused with the first, whereby the absorption coefficients of glasses are found to vary very appreciably with temperature in the region of wave-length close to the ultra-violet limits of transparency of the glass. The effect is immediately reversible, and over the range 10°–50° C., the relation absorption coefficient – temperature is strictly linear, and in all cases absorption coefficient increases with increase in temperature. The specimens of glass were kept at known temperature in a vessel with quartz windows top and bottom. Through this vessel water was passed, the temperature of which was controlled by a small electric heater.

3300 A.

Glass	Absorption coeff. per cm. thickness		Percentage variation per ° C.	
	3300 A.	3110 A.	3300 A.	3110 A.
'Vita'	0·121	0·578	0·48	0·38
Pilkington's 'White'—Sample 2	0·426	1·67	0·49	0·39
Patent plate—Sample 5	1·59	—	0·47	--
Pilkington's 'White'—Sample 4	0·482	—	0·38	---
Ordinary microscope cover glasses	1·69	6·10	0·34	0·24
Ordinary photographic plate glass	0·925	5·14	0·66	0·46

With the particular spectrophotometer used, only three wave-lengths were available, and assuming for the longest, namely, 4500 A., a negligible absorption for all the glasses used, the values of absorption coefficient per cm. thickness and percentage increase per degree centigrade (shown in the accompanying table) were obtained for light of 3300 A. and 3110 A.

During a control experiment without glasses but with tap water at various temperatures, the spectrophotometer readings were constant.

The percentage change of absorption coefficient with temperature was found in the first three widely different glasses to be constant for a given wavelength, and it was thought that if this should hold for all glasses, then the effect might be due to a single impurity—possibly iron—present in them all in varying amounts. However, the later specimens gave results which were rather different, so it seems that more than one substance in the glass contributes to the effect.

It follows from the above results that, for work involving the absorption of ultra-violet light by glass filters, it is necessary to keep the filters at a known temperature constant to about 1° C. for reasonable accuracy to be obtained.

This effect may be known to some people, but it does not seem to be generally recognized, and little reference to it can be found in published works.

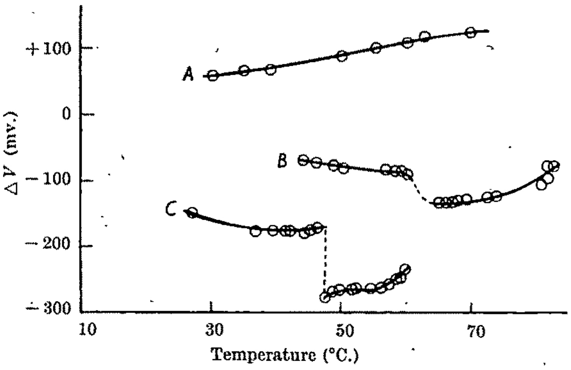
Surface Potential Changes of Thin Films in the Transformation Liquid to Solid

In an investigation on the oxidation and polymerization of polymerizable glycerides, it appeared feasible to follow the polymerization accompanying the oxidation by measuring the change of potential at the gas/liquid interface, as the liquid phase passes abruptly to a solid or gel phase. This has been successfully accomplished. From this it was considered that similar changes in surface potential might attend the change from liquid to solid of pure polar materials at the melting point.

Measurements have been carried out on two typical polar materials, stearic acid and cetyl palmitate, and for comparison purposes on a relatively non-polar material, paraffin wax. These were spread in thin films, about 1 mm. thick, on a polished platinum plate kindly supplied by the Mond



A, Paraffin wax, m.p. 60° C. *B*, Stearic acid, m.p. 65° C. *C*, Cetyl palmitate, m.p. 48° C.

Nickel Co. The potentials were measured by the usual method employed for following surface potential changes on unimolecular films spread on water, using a valve electrometer and a radioactive (polonium) electrode[1]. The accompanying figure shows the potential in millivolts as a function of temperature for the three materials. It is significant that the two polar materials exhibit an abrupt change at the melting point (within the experimental error) while the non-polar paraffin wax exhibits no abrupt change at the melting point. The recorded potentials are, of course, not absolute values since they involve various contact potentials inherent in the apparatus. The potentials recorded are the sum of these various contact potentials and the potentials arising at the boundary metal/film and film/air. Only the two latter sources of potential might be expected to show discontinuities at the melting points in the case of polar materials, since the passage from the liquid to the solid state will involve changes in molecular orientation.

The exact source of these potentials is not clear, but changes in orientation of polar molecules at phase boundaries might be expected to play a part, and the absence of any abrupt change in the case of the non-polar paraffin wax appears to be significant in this respect.

A Magnetic Study of the Effect of Bond Angle Distortion

The prediction[1] that diamagnetic nickel complexes would prove to be square co-ordinated has been verified in a number of different ways. The discovery of isomeric nickel glyoximes[2], the crystal structure of potassium nickel dithioxalate[3] and investigations of crystal optics[4] and isomorphism[5] of other diamagnetic nickel compounds have all borne out the existence of this correlation between structure and magnetic properties. All internal nickel complexes in which four nitrogen atoms are bonded to the metal atom have proved, on investigation, to be diamagnetic, and they may therefore be presumed to be square bonded. The nickel derivatives of various glyoximes[2], phthalocyanine[6] and protoporphyrin[7] afford examples of this type of complex. In these circumstances it becomes possible to investigate magnetically the question as to whether distortion from a square configuration gives nickel-nitrogen bonds sufficient ionic character to make a complex paramagnetic.

Porter[8] has shown that when certain substituted pyrromethenes (with methyl groups in the α position) function as chelate groups and attempt to assume a planar configuration, as with nickel, clashing between methyl groups must occur. In a complex containing two pyrromethene molecules attached to a single nickel atom, the Ni-N bonds must be forced from their normal coplanar disposition. This occurs in nickel *bis* ethyl 3 : 3′–5 : 5′-tetramethyl-pyrromethene-4 : 4′ dicarboxylate, the compound chosen for investigation. Susceptibility measurements show that the compound is paramagnetic and that the nickel atom has a magnetic moment of 3·2 Bohr magnetons. From this it may be inferred that forcing the Ni-N bonds out of the plane profoundly alters their character; they are no longer essentially covalent bonds involving the use of dsp^2 orbitals but are predominantly ionic in character.

Further details of this work will be published shortly. We are indebted to Dr. R. Lemberg for providing facilities for carrying out this and related work.

History of the Vacuum Flask

Lord Rayleigh states in Nature of April 20 that Dewar's assistant, Lennox, made the first vacuum flask. As one of the few survivors directly concerned with the production of the vacuum flask from its inception, I wish to place on record the facts as I know them.

I first met C. E. Muller, the expert glassblower, in 1887 at 147 Gower Street, where he lived with his brother, Emelius, who was established there as "Artificial Human Eye Maker". At that time I had a laboratory in Charlotte Street, Fitzroy Square, W., for which Muller made the chemical apparatus. At my suggestion Muller began business, in 1887, at 26 Charlotte Street, moving to next door (28) in 1888. In 1891 he removed to 148 High Holborn, the lease of which I helped him to negotiate, where he continued in business until about 1910, with such success that he was able to retire.

From 1887 until about 1900, when a Mr. Orme joined him as partner, I was on intimate terms with him in the conduct of his business. When Dewar in 1892 asked Muller to make for him the first double-walled vacuum vessels, they were all made of clear glass, which is sufficient proof, I think, that they were the earliest made. It was then suggested that the internal surface should be silvered, to reduce radiation influx; as Muller had no experience in this, I instructed him in the technique, and actually silvered the first two or three vessels myself.

The fact that Lord Rayleigh was unaware that Muller was in London at this time suggests to me that it must have been a considerable time after 1892 when Lennox demonstrated to him how double-wall vacuum vessels were made. By this time Lennox may have learned the technique of making them from Muller, as these vessels are very difficult to make, and no ordinary glassblower, *at that time*, would be capable of doing so.

Economy in Education

THERE is one way in which a great many of our public schools might well economize, and that is in the building and equipment of science laboratories such as are in use at the present time. My teaching experience is confined to public schools only; but I give it as my opinion that the money spent on costly apparatus and equipment is in many cases sheer waste and out of all proportion with the science which can and should be taught in schools.

I do not stand alone in this matter, for Mr. O. H. Latter, probably the pioneer of the teaching of biology in schools, writes in the preface of "Readable School Biology" (Bell, 1926): "I hold that with classes taking Biology as a part of their *general education*, personal practical work by the pupils themselves is sheer waste of time and money".

Much of the responsibility for this waste lies at the door of the science teachers themselves, but I think that still more lies at the door of the Board of Education.

A. G. LOWNDES.

Points from Foregoing Letters

P. J. G. Mann and J. H. Quastel show that the addition of vitamin B_1 to isolated polyneuritic pigeon brain increases the rate of synthesis of acetylcholine when the brain is incubated aerobically in a bicarbonate – pyruvate medium containing a relatively high concentration of potassium ions. No such increase occurs when the vitamin is added to normal pigeon brain examined under similar conditions.

By successive digestion with pepsin and trypsin, an enzyme-resistant phosphopeptone of constant composition has been isolated by M. Damodaran and B. V. Ramachandran from casein in the form of its barium salt. In contrast to a similar phosphopeptone obtained by Rimington, which was claimed to contain hydroxyglutamic acid, hydroxyaminobutyric acid and serine, the substance isolated consists of glutamic acid, *iso*leucine and serine.

Normal adult and embryonic tissues explanted *in vitro* begin to proliferate after a certain latent period which varies with the age of the organism. L. Doljanski and R. S. Hoffman have investigated the latent period of neoplastic tissue (rat sarcoma and Rous chicken sarcoma) and found that tumour explants commence proliferating *in vitro* after a latent period which is very much shorter than that of normal adult tissue. In about half the experiments tumour tissue started to grow practically without [illegible] latent period.

H. Loewenthal and F. L. Hopwood find that fully capsulated young cultures of hæmolytic streptococci, when exposed to ultrasonic vibrations, provide a better antigen than overnight cultures. They point out, however, that since the disintegration of streptococci by ultrasonic vibrations liberates serologically active material from cocci possessing no demonstrable capsule as well as from the fully capsulated cocci, the observations cannot be taken as conclusive proof that the type-specific antigen of streptococci is situated only in the capsule.

Three skulls of very young individuals of the Indian antelope (*Antilope cervicapra*) showed the presence of rudimentary upper canine teeth, which in one case had not reached the surface of the maxilla. J. Ritchie suggests that this evidence supports Forsyth Major's belief that rudimentary canine teeth may be present in all fœtal and most very young antelopes, notwithstanding the evidence recently adduced by Lönnberg.

R. S. Krishnan and T. E. Banks have separated chemically the recoil fragments produced from uranium fission under deuteron bombardment and have shown that some of the activities agree with those produced by neutron fission of uranium. They have also obtained evidence of deuteron-induced fission in thorium. Excitation function measurements and chemical separation of the recoil fragments have been carried out for this case also.

The effect of temperature in the ultra-violet transparency of various glasses has been examined in detail by W. J. Arrol for two wave-lengths close to the limits of transparency in this region. A strictly linear relation holds between absorption coefficient and temperature over the range 10°–50° C.

Measurements of phase boundary potential during the melting of certain solids by C. Ockrent and W. H. Banks show that the transformation is accompanied by abrupt changes in potential.

D. P. Mellor and W. H. Lockwood have measured the magnetic susceptibility of a nickel compound in which the normal planar distribution of the bonds about the nickel atom is prevented by steric interference. They claim that the distortion changes the character of the bonds from being essentially covalent to bonds essentially ionic in character.

RESEARCH ITEMS

New Shrines on the Gold Coast

A RELIGIOUS development, which is in effect a reversion to a traditional form of belief, now taking place on the Gold Coast is described by Miss M. J. Field, Government anthropologist (*Africa*, 13, 2; 1940). In the traditional society of the Gold Coast, which still survives in certain isolated areas, the governmental unit was the extended family with the head as both ruler and priest of the family god. So also in the confederated family groups, still existing, religious organization and governmental organization are one. In other parts of the Gold Coast, for example, Akim, this traditional form has been overthrown. From the end of the seventeenth century, colonists and refugees set up a military organization which has now, with the development of the cocoa industry, become financial. The earlier cults completely disappeared. Recent social changes, more especially a great increase in venereal disease, detrimental to fertility, and marital infidelity among the women, have led to a remarkable increase in belief in the power of the witch. New protectors against this malevolent force have been sought in the Northern Territories, where there is no witchcraft, because of the power of the traditional indigenous deities. Their worship has therefore been introduced into the Gold Coast country as a protective magic, subordinate shrines being set up. All over Akim these shrines have been instituted, and some have gained a far-flung reputation. It is suggested that the prevalence of these shrines indicates a reversion to a type of organization similar to that which was broken up by intrusions two hundred years ago.

Radium and Radon Therapy

A SECOND edition of "Physical Aspects of Radium and Radon Therapy", published in May, 1939, by the Ministry of Health of the Commonwealth of Australia, goes over some ground that is already familiar; but there are several new features, notably those on the technique of radon filling and on the comparative advantages of radium and radon considered from economic and technical points of view. There is also an interesting attempt to distinguish between the total dose of radiation given to the tissues and the effective dose that results; the difference only arises because of the power of the tissues to recover from the effects of radiation while it is actually being given. The authors, C. E. Eddy and T. H. Oddie, develop this matter on simple mathematical lines, but in lieu of experimental data have to proceed as follows: "Now suppose that a dose of gamma rays delivered at any given instant decays in its effect on the tissues by x per cent in 24 hours. . . ." Granted the assumptions, the following conclusions are reached: "(*a*) The quantity of radon required to give the tissues the same residual dose R′ in any given time as is given by one milligram of radium, is slightly greater than that required to deliver the same dose R. (*b*) When radon is used the residual dose R′ is higher for a longer period of time than is the case when radium is used."

Cytology of Carcinogenesis

DR. PULLINGER (*J. Path. Bact.*, 50; 1940) has studied the early stages of tumour formation by polycyclic compounds. The carcinogenic compounds evoke a characteristic reaction on the second to fourth day after application; the cells and nuclei swell and the cytoplasm becomes vacuolated. This reaction is followed by multiplication of cells with progressive increase in size of cells and nuclei. Cytoplasmic degeneration appears in some of the cells while others show signs of recovery. Related non-carcinogenic compounds do not appear to produce this reaction, which may be specific.

Curious Nesting-place of Kittiwake

EVENTS in Norway have made the March number of *Naturen* the last we are likely to receive for some time to come, for the spreading of scientific news in popular form among Norwegian naturalists must give way to more vital affairs. Along with articles dealing with such varied subjects as the newer geophysical methods of assessing the underlying rock formations, and the occurrence of the jelly-fish *Rhizostoma octopus* in Norwegian waters in the Atlantic Drift, occurs an interesting account of a modification of nesting-place in the kittiwake. Instead of the usual sites chosen on the narrow ledges of sea-cliffs, Knut Schmidt-Nielsen describes how in 1928 kittiwakes (*Rissa tridactyla*) began to prospect the ledges of a wooden brewery at Røst, and how by the summer of 1939 twenty-one pairs were nesting in regular rows where suitable shelves were present on the building. The selection of so curious a site is the more remarkable because it was in close proximity to a constant stream of traffic, boats and motor-boats (*Naturen*, Bergen, 94, March 1940). An excellent photograph shows about fifteen of the nests, most of them occupied.

Stratification of Foraminifera in Marine Deposits

H. G. STUBBINGS has examined six cores obtained by the John Murray Expedition in the Southern Arabian Sea (John Murray Expedition 1933–34. *Sci. Rep.*, 3, No. 3. "Stratification of Biological Remains in Marine Deposits". British Museum (Natural History), 1939). Only the Foraminifera are described in this report, the object being to demonstrate 'climatic' classification in the Arabian Sea similar to the findings of previous workers in the Atlantic. Many pelagic species occurred and a few benthic species. Of the pelagic species *Globigerina bulloides* and *Globorotalia menardii* are the commonest, and occur in inverse relationship. *Globigeri*[illegible] *bulloides* is mainly a cold-water species and *G*[illegible]*orotalia menardii* is an inhabitant of tropical and subtropical waters. It has thus been found possible to use these two species as a guide to changes of climatic conditions in the past. Four 'cold zones' are shown in the longest core, containing *Globigerina bulloides* in quantity, and the intermediate zones with relatively more *Globorotalia menardii* probably represent warmer interglacial periods.

Inheritance of Instinct

VERY young setters will instinctively 'point'; Siamese cats are natural retrievers, a character which is known to be dominant in cats; the wooler rabbit jumps in the air and shaker mice turn somersaults when frightened. C. E. Keeler and H. C. Trimble (*J. Hered.*, 31, 51–54; 1940) describe pedigrees of Dalmatian hounds which indicate that the position under or behind the coach automatically taken by the dog is controlled by heredity. Several interesting examples of instinctive reactions in untrained animals are given. 24 good following dogs and 3 poor followers descended from parents both of which were good coaching dogs. On the other hand, the crosses bad × good and bad × bad produced 7 good, 9 bad and 2 bad dogs respectively. One bitch which always ran with her head between the horse's legs was mated to a dog that trailed behind the carriage. The three pups trailed badly. The same bitch was mated to a dog which ran forward of the front axle. Of their resulting progeny, 6 pups ran in the forward position, and one insisted on running with his nose touching the horse's hind legs (see also NATURE, 144, 671; 1939).

Chromosome Numbers of British Plants

IN connexion with the recent co-operative work in taxonomy, genetics, and cytology, P. Maude (*New Phyt.*, 39, 17–32; 1940) has investigated the chromosome number of numerous British wild plants. Such plants as *Chenopodium album, Arum maculatum, Allium Babingtonii, Corydalis bulbosa, Sieglinga decumbens* ($2n = 124$), *Kœleria vallesiora, K. gracilis* ($2n = 28$ and 30), *Puccinellia* (*Glyceria*) *maritima* ($2n = 63$), various species of Festuca and Bromus and other plants were found to be polyploid. A curious feature was that seven plants of *Spirea filipendula* ($2n = 15$) from different sources had an odd number of chromosomes.

Cryolite as an Insecticide

FLUORINE compounds have so far proved the most effective substitutes for arsenical insecticides. Sodium fluosilicate, a by-product in the manufacture of acid phosphate, is being used extensively in the United States for baits in the control of grasshoppers and cutworms. Cryolite, a compound of sodium, aluminium and fluorine mined in Greenland, is very effective against fruit pests such as codling moth and apple flea weevil and for vegetable pests such as flea beetles. S. Marcovitch writes (*Amer. Fruit-grower*, Feb. 1940) on the use of cryolite in apple orchards. The mineral, which is used mainly in the manufacture of aluminium, is ground to a fine dust occupying about 50 cub. in. to the pound. Like lead arsenate, it acts as a stomach poison but is more effective than the former against codling moth. It has less sticking power, however, and is therefore most effective in dry seasons. It has no poisonous effect on the soil, a great advantage over arsenical compounds, which have rendered some soils in America unfit for crops. Another advantage is that [illegible] is non-poisonous in the amount likely to remain [illegible] spray deposit on apples. The amount allowed by law is 0·02 grain per lb. Fluorides present in drinking water to the extent of 1 part per million cause mottling of the teeth of residents in some parts of Arizona. Cryolite on apples has been shown to be free from this objection. In contrast to lead arsenate, cryolite appears to have no injurious effect on apple foliage. As many as seven applications in a season have been given without causing defoliation or damage to fruit. In some seasons, however, damage to peach fruits known as 'tip end injury' has occurred.

Irradiation of 7-Dehydrocholesterol

STEROLS which have received most attention in respect of photochemical conversion into antirachitics are ergosterol and cholesterol, associated with lower plants and with animal materials, respectively. Crystalline ergosterol may be regarded as the precursor of vitamin D_2 (calciferol); crystalline cholesterol does not itself constitute a significant provitamin but its derivative, 7-dehydrocholesterol, when exposed to ultra-violet radiation, is converted into vitamin D_3, found only in animal tissues. J. W. M. Bunker, R. S. Harris and L. M. Mosher (*J. Amer. Chem. Soc.*, 62, 508; 1940) have examined the photochemical activation of crystalline 7-dehydrocholesterol in ether by monochromatic ultraviolet radiation. With wave-lengths 2483, 2537, 2652, 2804 and 3025 A., the activation is substantially uniform per quantum of energy supplied. On a quantum basis, the activation by 2967 A. is significantly greater than for any other wave-length examined, except possibly 2894 A. The activation by 2894 A. appears to be intermediate between that of 2967 A. and the other wave-lengths examined. No demonstrable antirachitic properties were produced by 3130 A. The superior effectiveness of 2967 A. parallels the significant superiority of this wave-length in inducing healing upon direct irradiation of depilated rachitic rats, which supports the view that 7-dehydrocholesterol is a significant precursor of vitamin D in the skin.

Spectrophotometric Gradients of some Northern Stars

AN important paper entitled "Relative Gradients of 250 Stars determined at the Royal Observatory, Greenwich" has been published by H. Spencer Jones (*Mon. Not. Roy. Astro. Soc.*, 100, 3; January 1940). The catalogue of the spectrophotometric gradients of the 250 stars includes most northern stars brighter than 4·5, the H.D. spectral types of which are *Oe5*, *B* or *A*, as well as many fainter ones of these types and a selection of bright *F*- and *G*-type stars, and completes the Greenwich colour temperature programme. The previous results were given in "Observations of Colour Temperatures of Stars", 1926–32, and a description was given in this volume of the methods used in determining the gradients. These differ very slightly from those adopted in the later programme. The 30-inch reflecting telescope has been replaced by the 36-inch Yapp reflector, and in the case of fainter stars small corrections have been applied to allow of the difference in exposure time between the stellar and the calibration exposure. More sensitive Ilford 'Astra VIII' plates have been utilized in the later work, and it is hoped that full details of the scheme will appear later in a Greenwich volume which is delayed in publication owing to the War. As a definite value of the quantity needed to convert absolute to relative gradients is not yet available, relative gradients only are given in the catalogue. In the previous work the zero to which the gradients were referred was the mean of nine specified stars of H.D. type *A*0, and it is thought that the value for the Greenwich zero-point may be about 1·10, which corresponds to 15,600° K., but this will be determined later. The absolute values of the gradients and hence of the 'temperatures' will be obtained when the Greenwich zero-point is finally settled.

MUCOLYTIC EFFECT OF NATURAL AND ARTIFICIAL SPREADING FACTORS

MUCOLYTIC EFFECT OF SEVERAL DIFFUSING AGENTS AND OF A DIAZOTIZED COMPOUND

By PROF. G. FAVILLI, University of Modena

CHAIN and Duthie[1] have recently reported that a purified testis extract, which contains the so-called 'spreading factor' that increases the permeability of the tissues, has a remarkable mucolytic activity: the viscosity of synovial fluid falls very rapidly when it is mixed with a tenth of its volume of the extract. The loss of viscosity is followed by liberation of N-acetyl glucosamine and reducing substances. Bacterial filtrates in which the spreading factor is present were found to have a similar action on mucin. These observations suggest that the diffusing and mucolytic activities may be due to the same factor, and it is of interest therefore to determine whether diffusing factors from other sources show a similar mucolytic effect. The solutions to be tested have been added to fresh bovine synovial fluid in a proportion of one to ten volumes and the mixtures incubated at 38° C. The following facts have been observed.

Snake venoms, which possess a very high diffusing activity[2,3], show a marked mucolytic effect. Venoms from the following species have been tested: *Vipera aspis*, *Vipera ammodytes*, *Bothrops jararaca* (former name: *Lachesis lanceolatus*), *Lachesis alternatus*, *Echis carinatus*, *Crotalus terrificus*. The dried venoms, dissolved in saline solution, cause a rapid fall in the viscosity of synovial fluid, measured in an Ostwald viscometer. The fall of viscosity may be almost immediate when venoms are used in dilutions varying from 1 : 1000 to 1 : 10,000, according to the species of snake. This effect was evident in dilutions as high as 1 : 100,000.

The mucolytic activity is almost completely suppressed when the solution of venom is heated for thirty minutes at 70° C. before it is added to the synovial fluid. The activity of the enzyme is also completely suppressed when specific antiserum in a convenient amount is added to the solution of venom: the addition of normal horse serum, on the contrary, has no inhibitory action.

Aqueous leech extracts which, as Claude[4] reported, show marked diffusion in the dermis, proved to be actively mucolytic. An aqueous extract of the heads of several leeches was prepared by grinding this material with quartz sand in a mortar and adding saline solution in an amount equivalent to 1 c.c. per head. After centrifugation, the supernatant fluid was mixed with synovial fluid, the viscosity of which fell to a value not much higher than the viscosity of water after a short incubation.

The *p*H appears to have a great influence on the mucolytic action; experiments have been made with testis extract, purified by the method described by Mannozzi-Torini[5], and snake venoms prepared with buffer solutions of different *p*H value instead of saline. It has been observed that testis extract and snake venoms are most active at about *p*H 5·0; the activity gradually decreases and can be practically inhibited, at least in the case of snake venoms, when the *p*H is adjusted to 8·5. These results are in agreement with those of McClean[6].

Commercial preparations of Frey and Kraut's *kallikrein* (Padutin Bayer) have a certain diffusing activity[7] which appears to differ in character from that of the other spreading factors so far known[7,8]: no mucolytic effect could be detected with this substance. The observations reported above, taken in conjunction with those of Chain and Duthie, indicate that all the naturally occurring diffusing factors so far tested possess mucolytic activity.

As Chain and Duthie point out, the action of diffusing factors may be explained by the presence of a mucin-like inter-fibrillar substance in the collagen of the dermis in which these factors are active[9]. In order to support this hypothesis it seemed desirable to ascertain whether certain artificial compounds possessing diffusing power have the same mucolytic effect as the naturally occurring diffusing factors.

Following the instructions given by Claude[10], who first observed the diffusing properties of an azoprotein obtained by coupling diazobenzenesulphonic acid with serum or gelatin, this compound has been prepared and coupled with horse serum. The reaction of the azoprotein was adjusted as nearly as possible to *p*H 7·0 by the addition of normal acetic acid, this operation being controlled electrometrically; it was then buffered by adding 2 c.c. of phosphate buffer at *p*H 7 to 4 c.c. of azoprotein. The final solution possesses marked mucolytic activity, when tested on synovial fluid. The fall of viscosity is not abrupt; it is most marked in the first hour, and continues gradually until the fourth hour, as is shown in the following experiment.

FALL OF VISCOSITY, EXPRESSED IN TIME OF FLOW THROUGH A VISCOMETER IN SAMPLES OF 3 C.C. TAKEN AT DIFFERENT INTERVALS FROM 30 C.C. OF SYNOVIAL FLUID INCUBATED AT 37° WITH 3 C.C. OF AZOPROTEIN BUFFERED AT *p*H 7·0

Distilled water	7 min.	5 sec
Normal synovial fluid added with 1/10 vol. of distilled water	27 ,,	5 ,,
Synovial fluid added with 1/10 volume of azoprotein: immediately	26 ,,	
Synovial fluid added with 1/10 volume of azoprotein after 15 min.	20 ,,	
,, ,, ,, ,, ,, ,, ,, 30 ,,	17 ,,	5 ,,
,, ,, ,, ,, ,, ,, ,, 45 ,,	15 ,,	5 ,,
,, ,, ,, ,, ,, ,, ,, 60 ,,	13 ,,	5 ,,
,, ,, ,, ,, ,, ,, ,, 90 ,,	12 ,,	
,, ,, ,, ,, ,, ,, ,, 120 ,,	11 ,,	5 ,,
,, ,, ,, ,, ,, ,, ,, 180 ,,	10 ,,	5 ,,
,, ,, ,, ,, ,, ,, ,, 240 ,,	10 ,,	

Comparative experiments made with azoprotein and with naturally occurring diffusing factors have shown that the mucolytic effect of the latter is much quicker than that of the former substance, the fall in viscosity being complete after thirty minutes if the diffusing factors are sufficiently concentrate[illegible] (for example, *Vipera aspis* venom diluted 1 : 10[illegible] This result accords with the fact that the diffusion of naturally occurring factors, when tested in the dermis of the rabbit, is much more rapid than the diffusion of azoproteins; this might, therefore, be considered as indirect support for the hypothesis that diffusing factors act by destroying the mucin-like inter-fibrillar substance.

In several experiments the diazobenzenesulphonic acid was neutralized, immediately after its preparation, with $2N$.NaOH solution, buffered with phosphate buffer at pH 7, and tested on synovial fluid: the mucolytic activity of this compound is practically the same as that of the acid coupled with serum.

The mucolytic effect of the diazobenzenesulphonic acid, both in the form of azoprotein or of sodium diazobenzenesulphonate, is little influenced by the pH: the maximum activity has been observed at a pH of about 5·0, the minimum at pH 7·0, whereas there is a slight increase of activity at pH 8·5. This fact needs further investigation.

These results indicate that both the artificial and naturally occurring diffusing factors so far tested exhibit similar mucolytic activity, and support the hypothesis that the action on tissue permeability may be due to enzyme activity on the mucin-like interfibrillar substance.

Some difficulties have been encountered in attempting to decide whether the chemical action of diffusing factors on mucin, as measured by the liberation of reducing substances, is identical whatever the source of the factor. This point is of special interest in the study of the action of diazotized compounds, and the experimental difficulties encountered are under investigation.

MUCINASE AND TISSUE PERMEABILITY

By D. McCLEAN and C. W. HALE
Lister Institute of Preventive Medicine

AQUEOUS extracts of mammalian testis contain a 'spreading' factor which dramatically increases the permeability of the skin to injected fluids[1]. This factor is associated with the germinal epithelium and can be extracted from spermatozoa. Factors with similar diffusing properties have been obtained from the most diverse sources, for example, from filtrates of staphylococcus and streptococcus[2], from organisms of the gas gangrene group and virulent pneumococci[3], from extracts of malignant tissues[4], from snake and spider venoms[5] and from leech extracts[6]. Many of these factors have been partially purified by various methods[7], but no one had succeeded in elucidating the mechanism whereby this diffusing effect is produced until Chain and Duthie[8] made the important observation that purified testis extracts exhibit a remarkable mucolytic activity characterized by a rapid fall in the viscosity of the substrate and the liberation of reducing substances.

It was obviously important to confirm the observation of Chain and Duthie, to determine whether diffusing factors from other sources exhibited a similar mucolytic activity and to make a comparative study of these enzymes. During the progress of this work, Meyer *et al.*[9] reported the hydrolysis of hyaluronic acid by bacterial enzymes, and recently a paper appeared by Robertson *et al.*[10] describing an enzyme derived from filtrates of *Cl. welchii* which hydrolyses synovial fluid; these authors had not connected the mucolytic activity of their preparations with the action on the permeability of the tissues.

In our earlier experiments vitreous humour was used as substrate, but in view of its spontaneous loss of viscosity on storage this was replaced by preparations of mucoprotein from umbilical cords; this can be purified by the method described by Meyer and Palmer[11]. Viscosity estimations were performed with buffered solutions of standard salt concentration in an Ostwald viscometer in a water bath at 34° C. N-acetyl glucosamine was estimated by the method of Morgan and Elson[12], and total reducing substances by the method of Hagedon and Jensen. Diffusing activity in the skin was estimated by intracutaneous injection using isotonic hæmoglobin solution as the indicator of spread.

We have confirmed the mucolytic activity of testis extract reported by Chain and Duthie; preparations of the diffusing factor purified by the method of Morgan and McClean and by those of Madinaveitia show similar activity. Purified preparations of the diffusing factor from *Cl. welchii* and *Cl. œdematis maligni* (*Vibrion septique*) are extremely active. Filtrates from a toxigenic strain of staphylococcus and from a virulent type 1 pneumococcus showed activity of the same order. All these organisms produce immediate diffusion in the dermis. On the other hand, filtrates from a virulent strain of *S. typhi*, from *Cl. tetani* and from *C. diphtheriæ* which produce no diffusion also contain no mucinase. The activity of the filtrate from virulent type 1 pneumococci is of interest since one of us[3] has reported that the same strain rendered avirulent by cultivation in immune serum loses its diffusing power; on the other hand Meyer *et al.* obtained their enzyme in the autolysate of a "non-encapsulated non-type-specific variant" of a type 2 strain and drew a distinction between their pneumococcal enzyme which was bound to the cell structure and that of *Cl. welchii* which was free in the fluid medium.

Russell's viper venom, which diffuses in the dermis, causes a rapid fall in the viscosity of mucoprotein. Since this venom promotes the coagulation of hæmophilic blood, and the chemical constitution of heparin is closely allied to that of muco-polysaccharide, it was of interest to determine whether this venom and the mucinases from testis or from bacteria exerted any destructive effect on heparin. So far as we have been able to determine by indirect experiments using the coagulation time of heparinized plasma as an indicator of the integrity of the heparin molecule, none of these substances has any direct action on heparin. This confirms the observation of Meyer *et al.* that their bacterial enzymes do not hydrolyse heparin.

The enzymes obtained from testis extract, from all the bacterial enzymes so far tested and from viper venom are most active at about pH 4·5. The rate of the reaction decreases sharply on the acid side of this and more gradually as the pH approaches neutrality.

The mucolytic activity of the bacterial enzymes is completely inhibited by appropriate antisera. Sera had been prepared against the purified diffusing factors of *Cl. welchii* and *Vibrion septique*. It has already been shown[3] that such sera neutralize the diffusing activity in the dermis and that the immunized animals are themselves resistant to the diffusing activity. This neutralization is strictly specific. We have now been able to establish that these sera completely inhibit the action of the homologous enzyme on the viscosity of the substrate and the liberation of reducing substances; there is no cross neutralization of this activity.

It is of considerable interest that, although these enzymes cause an immediate fall in the viscosity of the substrate, no reducing substances can be detected for some hours. With a preparation of the diffusing factor of *Cl. welchii*, which causes a marked fall in viscosity in a few minutes, only a trace of N-acetyl glucosamine can be detected after four hours and the maximum is not attained until after 18–24 hours incubation. At first it was thought that enzymes from different natural sources differed qualitatively as well as quantitatively in their capacity to liberate reducing substances; when, however, the concentration of enzymes from testis, *Cl. welchii* and viper venom was adjusted so that the reaction times for the reduction of viscosity were comparable, it was found that the amount of enzyme necessary to liberate detectable reducing substances was approximately the same whatever the source. The time lag in the liberation of reducing substances compared with the fall in viscosity suggests that two separate mechanisms may be involved. This possibility requires further study.

We have confirmed Favilli's observation, reported above, that diazotized compounds reduce the viscosity of mucin. We have encountered the same difficulties as he has in deciding whether N-acetyl glucosamine or other reducing substances are liberated by these preparations. These difficulties arise from the coloured nature of the diazotized compounds and the difficulty of removing the soluble protein. Preliminary experiments to overcome these difficulties indicate that no reducing substances are liberated, but these observations require confirmation.

Robertson *et al.*[10] state that the spontaneous loss of viscosity of vitreous humour is due to the activity of vitamin C. We have examined the diffusing and mucolytic activities of ascorbic acid in freshly boiled buffer at *p*H 7·0 and with the addition of one and two molecular equivalents of hydrogen peroxide. All three preparations cause a rapid fall in the viscosity of the substrate, the activity of the preparation with one equivalent of hydrogen peroxide being slightly greater than either of the others. No N-acetyl glucosamine could be detected following the fall in viscosity. The increased diffusion in the dermis following the injection of these substances is marked, but it is of the same type as that caused by diazotized compounds; that is, the increase is not apparent in the first few minutes but develops during a period of three hours. The preparation with one equivalent of hydrogen peroxide spreads over a greater area than either of the others. Thus the mucolytic activity of ascorbic acid and its oxidation products is also associated with an increased diffusion in the dermis.

An explanation of the physiological function of the mucinase in testis extract and spermatozoa is provided by the observation of Kurzrok and Miller[13] that semen contains a mucolytic enzyme whereby the spermatozoa are enabled to penetrate the plug of mucus normally present in the cervical canal of the uterus. The part played by bacterial mucinase in the metabolism of these organisms in artificial culture and on their invasive properties in the tissues is under investigation.

APPLICATIONS OF ELECTRICITY IN IRON AND STEEL WORKS

A REVIEW by H. G. Weaver of the progress made in the applications of electricity in iron and steel works during the last four years appears in the March issue of the *Journal of the Institution of Electrical Engineers*.

It appears to be now admitted that whereas Ward-Leonard control affords the most efficient method of providing the drive for the hoist and long-travel motions, the additional weight involved in the carrying of the conversion set on the crab is considered to outweigh its advantages, and a plain direct-current series drive has proved the most popular, the motors being of the steel-clad mill pattern, with roller bearings and split frames.

The main point of interest with recent installations of drives for coal-handling plant is the universal adoption of totally enclosed, fan-cooled motors. The controls have a system of sequence interlocking, which ensures that the stopping of certain conveyors will always automatically ensure the stopping of any other conveyors that are feeding them. More attention has recently been paid to the enclosure of the motors used in these plants, owing to the deleterious effect of the gases in the atmosphere. Special castings are used so far as possible, care being taken to see that they are free from porosity. Gas-proof gaskets and varnish are used for all frame and cover joints, and the windings carefully sealed with varnish and given extra coats of enamel.

In modern practice, the electrical equipment of blast furnace skip hoists is of the balanced type with two hoist motors on each. The weight of each basket empty is 12,000 lb., and the weight of each ore charge is 18,000–20,000 lb. The skip travel is 200 ft., at a speed of 450–600 ft./min. with an angle of incline of 53° from the horizontal. Each hoist is driven by two 200 h.p., 220 volt, direct-current, steel-works type motors, with a speed range of 0 to 570–762 r.p.m., by shunt control, which are forced ventilated by motor-driven blowers, mounted on the top of the motor frame. The two motors are connected in series across a 310 kw., 440-volt generator. The two skip hoists are arranged by switching to run from any two of three motor-generator sets, each set comprising a 310 kw., 440-volt generator driven by a 450 h.p., 3-phase, slip-ring induction motor.

New features are continually being introduced in the electrical operation of the winch equipment for the charging bells of blast furnaces. In a recent example, the large bell is driven by a 17 h.p., D.C., compound wound motor, and the small bell by a 10 h.p. motor of the same type and speed. In each case the motor speed when raising the bell is 540 r.p.m., and when lowering the bell 840 r.p.m. The control is by contactors and resistances, and is so arranged that in the event of slack cable, the bell-lowering contactors are opened and the winch is automatically reversed, so taking up the slack cable; then after a short time interval the bell is automatically caused to lower again, and this operation is repeated until the bell falls away freely or the operation is tripped by hand. There is also complete interlocking of the bells so that one bell must have completed its full travel and also sealed before the other bell moves.

The production of iron in a modern blast furnace is a continuous process, and the main essential of furnace operation is therefore smooth and regular working, with as few stops as possible. The most difficult problem has been the development of a satisfactory method of stopping up the iron tapping hole when required without the necessity of shutting off the blast. An electrically driven clay gun has recently been introduced for this purpose. The gun itself is suspended from a boom, which swings it into position and holds it against the hole while plugging is taking place. The gun is driven by a 20 h.p. motor and the boom by a 10 h.p. motor. They are switched direct on to the line without any overload or other type of protection, but limit switches are provided on both motions to prevent mechanical damage due to mal-operation of the controllers. The stalling torque of the 20 h.p. motor is 1·6 times full load torque and of the 10 h.p. 1·35 times full load torque, in each case when taking 2·5 times full load current at full line voltage. The boom motor is stalled when holding the gun against the hole. Very high ambient temperatures are encountered, and the motors have to be capable of withstanding stalling for half a minute under these conditions without excessive heating. They have 3 per cent nickel-steel shafts running in ball and roller bearings and are of welded steel construction throughout. The rotor windings consist of bronze bars secured in semi-enclosed slots, which are lined with anodized aluminium.

One plant for producing aluminium sheets has been equipped with a soaking pit furnace for ingots, a chain-conveyor furnace for slabs, cylindrical pit-furnaces for coil annealing and salt-bath furnaces for the heat treatment of sheets, all electrically heated and capable of dealing with aluminium. A particularly interesting development which is gaining ground more and more is the nitriding process, that is, the treatment of steel in an ammonia atmosphere, for the production of specially hardened parts.

Effects of Alcohol on the Human Body

A PAPER was read before the Royal Society on May 19 "On the Effects of Alcohol (*Ethyl Alcohol*) on the Human Body", by Dr. Parkes and Count Cyprian Wollowicz. The experiments were undertaken with a view of testing the physiological and especially the dietetic effects of alcohol. The subject was a healthy and very intelligent soldier of twenty-eight, 5 ft. 6 in. in height, weighing 134–136 lb., with a clean, smooth skin, a clear bright eye, good teeth, largely developed powerful muscles, and but little fat. As he had been accustomed to smoke, he was allowed half an ounce of tobacco daily, lest the deprivation of it might disturb his health.

From the general results of the experiments, it appears that any quantity over 2 oz. of absolute alcohol would certainly do harm to this man, and that as every function was performed perfectly without it, its use was wholly unnecessary. Yet the experimenters recognize "the great practical benefit that may be derived from the use of alcohol in rousing a failing appetite, exciting a feeble heart, and accelerating a languid capillary circulation, though, for these objects to be fulfilled satisfactorily, there is necessity for great moderation and caution".

Excessive and Depraved Appetite

PERHAPS the most extraordinary instance of excessive and depraved appetite on record is that of a French soldier, named Tarare, whose case is described in vol. XXI of the *Dictionaire des Science Medicales*. . . . At 17 years of age, when only weighing 100 lb., he could eat 24 lb. of beef in as many hours. From the day of his admission to the army, he was ordered quadruple rations, with pickings and waste meat, but often slipped into the dispensary to finish off a poultice or two. One day he was observed to seize a large cat; and, after sucking its blood, left, in a very short time, only cleanly picked bones, the hair being rejected in the course of about half an hour. He was fond of serpents and eels, swallowing them whole. On another occasion he consumed in a few minutes a repast, spread out for fifteen German workpeople, of milk, etc., after which he was blown out like a balloon. . . . He fell under suspicion of having eaten a child fourteen months old.

Whence come Meteorites?

PROF. N. S. MASKELYNE, F.R.S., has an article under this title in which he discusses views put forward by M. Stanislas Meunier, of the Jardin des Plantes, Paris. "Whether M. Meunier's theoretical conclusions are to be looked on with the same favour that we heartily accord to his practical work is what we are about to discuss".

M. Meunier supposes meteorites to be the shattered morsels of a satellite smaller than and perhaps subordinated to the moon, which has run its course and been broken up by internal throes of volcano and earthquake. The fragments are thought to be "careering in every direction, retrograde as well as direct, around our world" and falling to the earth's surface in the order of their densities. Thus iron masses have already descended, stony fragments are now arriving, and the character even of these will change as time goes on.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Monday, June 3

EUGENICS SOCIETY (at the Linnean Society), at 4.30 p.m.—Sir Bruce Bruce-Porter: "The Importance of the Child".

Tuesday, June 4

ROYAL INSTITUTION, at 5.15 p.m.—Dr. J. C. Spence: "The Feeding of Children".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN GENERAL ELECTRICAL ENGINEERING SUBJECTS—The Registrar, Municipal College, Portsmouth (June 8).

ASSISTANT SECRETARY OF EDUCATION—The Secretary for Education, Education Office, Barking Road, East Ham, E.6 (June 8).

LECTURER (WOMAN) IN GEOGRAPHY at the Bingley Training College—The Education Officer, County Hall, Wakefield, Yorks (June 10).

PROFESSOR OF METALLURGY—The Registrar, University College, Singleton Park, Swansea (June 11).

LECTURER IN EDUCATION—The Registrar, The University, Manchester (June 15).

LECTURER IN BIOCHEMISTRY—The Secretary, The University, Aberdeen (June 15).

PROFESSOR OF PHILOSOPHY in the University of Durham—The Registrar, 46 North Bailey, Durham (June 15).

STUDENT-DEMONSTRATOR IN BOTANY—The Principal, Royal Holloway College (University of London), Englefield Green, Surrey (June 29).

LECTURER IN BOTANY at the University of Cape Town—The Secretary, Office of the High Commissioner for the Union of South Africa, Trafalgar Square, W.C.2 (June 29).

SENIOR DEMONSTRATOR IN THE DEPARTMENT OF ANATOMY AND EMBRYOLOGY—The Secretary, University College, Gower Street, W.C.1.

ASSISTANT ENGINEER for the Malayan Public Works Service—The Crown Agents for the Colonies, 4 Millbank, S.W.1 (quoting M/9306).

THE REPUDIATION OF TRUTH

LEADERS of the various faiths delivered no uncertain message on May 26, the Day of National Prayer. With one voice they proclaimed the Allied cause to be the cause of freedom, truth, decency, and civilization.

"We are called," declared the Archbishop of Canterbury, "to defend our land and all that we hold dear within it, the wider Commonwealth that has so wondrously grown up around it, and our common heritage of freedom. Please God, this we shall do with all our might. But more than this —we are called to take our place in a mighty conflict of Right against Wrong. The ruthless invasions of peace-loving countries . . . have shocked the moral conscience of the world, at least where that conscience is free to act and speak. They lay bare a mere unbridled lust of power, under whose pressure all the old sanctities of truth, justice, mercy, and freedom are trampled under foot. To hesitate to brand this force which has been let loose upon the world as essentially evil would be to scorn all those moral standards which have been slowly and painfully established by mankind to give security and honour to the common life."

The Archbishop of York spoke to similar effect:

"The whole future history of Europe is at stake. Upon the issue of the conflict now joined the quality of civilization in the coming period depends. Our cause is the cause of freedom and mutual trust. With the German method of the broken promise goes contempt for the rights of the weak and the small. In such a world there can be no justice and no freedom."

Cardinal Hinsley, Archbishop of Westminster, uttered a vigorous denunciation of the Nazi regime:

"Peace has been murdered between nations because the party in power in Germany has avowedly cancelled truth from its programme, and has declared that our traditional Christian civilization is to be shattered by the might of the 'immortal Nordic race'. This new racial idolatry justifies to its votaries everything that the party wills for its own interests.

"For years past the youth of the German nation have been trained to use the discoveries and inventions of science, the fruits of industry, all their energies and talents, for the glory of total warfare. The gospel of pride and hate has been loudly preached to a large, receptive audience, unhappily comprising the mass of the German nation.

"Now at length Christians understand. No liberty is possible, no decency in human life, if a pagan people may subdue by its fury, and scourge with scorpions, the rest of mankind."

The Rev. Leslie Weatherhead, speaking in the City Temple, said:

". . . we are placed in the dreadful dilemma of either using the awful and ghastly weapon of war —a weapon chosen by our enemies after every other means of settling differences had been tried by us; or else enlarging—perhaps through the world—an area in which the Nazi evil is rampant; an evil in terms of broken promises, persecution of Christian and innocent people, the torturing of Jews, the denial of freedom, the suppression of truth, the imprisonment of pastors, the idolatry and supremacy of the State over all the rights of the individual, and perhaps worst of all, the training of little children, for generations ahead, to worship the idols of war, tyranny and oppression. Whatever we may feel about our own individual attitude to war, surely we are trustees for the generations to come, and must do our utmost not to let go the liberty which is *their* birthright."

The General Assembly of the Church of Scotland on May 25 affirmed that

"the present war is not merely a clash of nations, or merely a war of defence of national boundaries and Empire interests, but a mortal combat, the outcome of which will determine for many generations whether a large part of the world is to live under conditions of increasing freedom and honesty and truth and light. . . ."

The Chief Rabbi, Dr. Hertz, added his testimony:

"Nazism is the enemy of man, and our whole spiritual heritage—human brotherhood, human freedom, human decency—is being jettisoned by the pirate captains of the Nazi ship of State."

The World Congress of Faiths invited Hindu, Moslem and Buddhist leaders in India and Burma to join in the observance of the National Day of Prayer. Christians, Jews, Mohammedans and Hindus attended churches, synagogues, mosques and temples throughout Malaya on the same day.

Such unanimity is good evidence of the feeling of moral revulsion aroused among religious leaders of all faiths by the Nazi regime. It is clear that to them the present conflict is a struggle between civilization and barbarism. The reasons for viewing it in this light are evident. In what does civilization consist? Not in material wealth or productive power, not in the amenities and comforts of life, not in an advanced scientific technique, not in organization and machinery, not even in literacy and education. It is possible to enjoy all these benefits and be civilized, but it is no less possible to enjoy them and be barbarous. All these are external matters and do not touch the spirit of a community, and it is the spirit that is civilized or barbarous; other things are external trappings only, which may be impressive or comparatively poor; they scarcely matter. The civilized tradition seems to be characterized by, and based upon, a twofold reverence, that is, reverence for the human being as such, and for truth as a supreme value.

Where these two are respected, there civilization can be said to exist, even if there be only a modest material equipment. Neither laboratories nor factories, nor of necessity educational establishments, of themselves make a State civilized. It may be said that there have existed civilizations in which respect for the individual as such, and for truth, has been absent or in abeyance; but such cultures, if they have existed, have been alien to the tradition to which European civilization belongs, which is a tradition of tolerance and respect for truth and personality. These principles may often have guided actual practice very imperfectly; but however far the majority of people have fallen short, they have not actually turned their backs upon them. For that we have had to wait until the present generation, and now over a considerable area of Europe, traditional ideals are denied and scorned. The unique individual has now become a unit indistinguishable from other units, a cog in the military, industrial, or political machine. As a human being he has no rights as against the divine State, for the sake of which he exists, and from which he derives any trivial value that may inhere in him.

As for truth, both in the sphere of scientific theory, and in that of public and private behaviour, it has been cynically repudiated. Science, whether in biology, anthropology, psychology, or history has been subordinated to the needs of propaganda and imposed dogma. It is inspired no longer by the love of truth but by the interests and policy of a party. As for truth in action and behaviour, it has been displaced by the most cynical lying and treachery.

The present conflict, then, is one of civilization against its negation, and is a struggle for the preservation of individual freedom of speech and thought, as well as for the preservation of the sanctity of international and other agreements. There have been many suggestions that this is a war of Christianity against Paganism, but the fact would seem to be that the principles above described as being integral to civilization, namely, respect for the individual human being and for truth, are fundamental to all spiritual and moral religions—Christian and otherwise. Spiritual religion as an activity, not only of the group but also of the individual moral personality, involves the belief in freedom, and through its claim to establish contact between the devotee and the highest reality, involves the belief in the supreme value of truth. History shows how closely ideals of freedom and truth are bound up with spiritual and moral religion, and how prominent has been the part played by religion in the development of the civilized tradition—the tradition which is now under threat of demolition.

"The essence of all great religious systems," writes Sir Richard Gregory in his recently published "Religion in Science and Civilization"*, "is belief in the attainment of high ideals by devotion of service to them. Different individuals and communities require different doctrines and rituals to bind them together in worship of any kind, but all such formularies are only ancillary aids to a universal faith in the possibility of ascending towards the highest good by human endeavour."

* Religion in Science and Civilization. By Sir Richard Gregory. Pp. xiii+366+16 plates. (London: Macmillan and Co., Ltd., 1940.) 12*s*. 6*d*. net.

But not only is the present a struggle of true religion against idolatry (idolatry being the worship of the creature, for example, the State, and not of the Creator), but also it is a struggle of science against superstition. Not only is the Nazi doctrine of racialism, the *völkisch* philosophy of life, a pseudo-scientific dogma, but also the interpretation of evolutionary theory which the Nazis borrowed from Nietzsche, is crude and barbarous in the extreme, being what T. H. Huxley characterized and repudiated as "the gladiatorial theory of existence". Sir Richard Gregory, in the work above mentioned, quotes the noble and well-known passage from the Romanes Lecture in which those words occur, and adds, "This is the religious message of science; and all the evils of civilized life arise from the neglect of it by individuals and communities". Huxley's words have a singular relevance to-day:

> "The practice of that which is ethically best involves a course of conduct which, in all respects, is opposed to that which leads to success in the cosmic struggle for existence. In place of ruthless self-assertion it demands self-restraint; in place of thrusting aside, or treading down, all competition, it requires that the individual shall not merely respect but shall help his fellows."

On the human level, the further advance of the creative process demands co-operation rather than strife; thus the Nazi doctrine is reactionary as well as puerile. As for the glorification of war, popular in Nazi and some other circles, history and anthropology give little justification for it.

> "War represents only one phase in the development of civilization," writes Sir Richard Gregory, in a fine chapter on "The Cultural Aspects of War". "The contribution to advancement by peoples has not been through their warlike qualities, but by other thoughts and actions. The spiritual evolution of man, as represented by all that is best in civilization throughout the ages, and as inspired by the most exalted and ethical teachers, has not proceeded in its upward course through war but in spite of it."

But it is indeed in no spirit of glorification of war or race that the present struggle against the enemies of the European cultural tradition is being waged. The same writer makes this clear:

> "When the deliberate policy of a State is to impose its system by force upon people who wish to be free and have entirely different ideals, all believers in liberty of conscience and in the principles of natural cultural development should range themselves against such aggression."

It is a bitter tragedy; but yet more calamitous would be the tragedy if the cause of civilization were allowed to go by default.

PROGRESS OF THE ROYAL SOCIETY

The Record of the Royal Society of London for the Promotion of Natural Knowledge

Fourth edition. Pp. viii + 578 + 19 plates. (London: Royal Society, 1940.) 21*s*. net.

IT is twenty-eight years since, at the 250th anniversary of its incorporation, the Royal Society last issued an edition of its "Record". A possessor of the volume of 1912 will find, on studying that of 1940, that, although the two are almost uniform in outward and inward physique and necessarily have various parts of the text in common, there is so much that is new and valuable in the present edition that ownership of the earlier volume does not exempt him from having this also. Nor should its use be limited to scientific persons: any student of the general history of our time who ignores it, or treats cursorily what it can show him, would miss something that is vital to his theme.

Those topics which are common to both editions have evidently been examined *de novo*; and no sentence, passage, or section has been reprinted unless its facts, its phrasing, and its place in the newly told story have stood against the keen scrutiny which time and the recorder have exercised. The account of the foundation and early history, which occupied 47 pages in 1912, is matched now by 85 pages—Chapter i—on the rise and growth of the Society, in which new matter of the seventeenth century is introduced in a rearranged story, and wholly new sections describe the Society in the eighteenth century (10 pp.), the nineteenth (21 pp.), and the twentieth up to the recent breakdown of that remarkable period (12 pp.). The texts and translations of charters, and the statutes, formerly in the main text, are now transferred to appendixes, as are the lists of patrons, officers, medallists and lecturers, with the complete chronological and alphabetical lists of the fellows from 1663 until 1939 (some 6,000 in all), and an interesting table and graph of the numerical progress of the fellowship. These appendixes fill about 350 pages. The index of 9 pages is twice as long as that of 1912, and much more than twice as useful. Chapters ii–ix of the main text, covering about 130 pages, give notes on the charters and on the statutes, and describe lucidly the various funds and benefactions, the library and collections, the committees, and the publications: in all which accounts, there is maintained the nicest balance between fact and commentary, with just enough of the latter to cause the whole to cohere, and to enable the reader to see perspectives as they should be seen.

In other domains of human enterprise, it may often be noticed that a growing interest in the past marks a decline of real vigour in the present. That growth is manifest here; but emphatically not the decline. Indeed, even though the "Record" scarcely touches (except in the lists of the subjects of special lectures) upon the specific advances in science for which the Society has stood sponsor, the reader who notes those corporate activities which belong to the last twenty-eight years can scarcely fail to judge this period as being, in many ways, the most vigorous and fruitful in any of the four centuries which the Royal Society has helped to shape.

The last phrase is no hyperbole. But it is inevitable that scientific ideas and knowledge should always be anachronisms of anticipation, ahead of their historical date as this is measured by the calendar and assessed by the conventional historian; and therefore a far-sighted generation, that would cater for its own posterity's needs, does well if it encourages its scientific men. That our generation from 1912 until 1939 has not lacked persons of such foresight, as well as the means to exercise it, can be learnt from Chapter iv, and is seen at a glance in a very concrete way from the table on p. 78 in Chapter i: the Society's funds, which in 1900 were put at £169,445 and in 1913 at £179,735, in 1937 were put at £893,134. More than three-quarters of this capital is held for the direct aid of research, producing to this end an income exceeding £30,000 yearly—some thirteen times as much as was available in 1912—with which have lately been endowed the distinguished and productive professorships and studentships, of which the purposes and the holders' names are recorded in Chapter iv. Not only have the Society's own funds thus grown (though there is still much need for additions free from restrictions other than at the Council's discretion), but also the Parliamentary grants-in-aid which the President and Council administer are much greater than formerly: for example, that for scientific investigations is now £7,000 annually, that for scientific publications £2,500; and other responsibilities have also been accepted.

The nineteen illustrations in the volume have been thoughtfully chosen; and the reproduction of portrait-subjects at full length is an artistic improvement upon the practice of 1912. A reviewer may be suspect if he have *no* cavil: all I can do to meet this is to note that an interesting part of John Wallis's letter of 1696–97 has been omitted; and, concerning Plate 11, to question whether the design of John Tate's watermark (not "wire-mark", by the way, which is a different thing) is properly described. But these things matter nothing: the review should end as it began, adding only the fact, modestly mentioned in the President's preface, that the preparation of this "Record" was mainly in the hands of Sir Henry Lyons, lately treasurer of the Society.

J. I. O. MASSON.

BIRD PORTRAITS

Intimate Sketches from Bird Life

Written and Illustrated by Eric J. Hosking and Cyril W. Newberry. Pp. xx+104+53 plates. (London: *Country Life*, Ltd., 1940.) 5*s*. net.

THE study of birds has long absorbed the mind of man. Since the days of Willoughby, through the centuries to Bewick and St. John, and down to our own time, ardent naturalists have not been wanting to chronicle the habits of birds. The camera has brought an added, though harmless, weapon into the armoury of these naturalists. Had the camera been invented in St. John's day he might perhaps have laid aside his gun, and photographed, rather than shot, the ospreys and other rare Highland birds which he, keen naturalist though he was, did not hesitate to slay.

It is good to think that we now protect and study our remaining birds; by means of photographs their shy lives are brought vividly and faithfully before a large public prevented from seeing these birds (or at all events the rarer ones) themselves.

One of the early pioneers in bird photography, and undoubtedly the best known, was Richard Kearton, whose enthusiasm was tremendous. He photographed birds from a stuffed ox, sometimes from a stuffed sheep. Cameras, and photographic plates and films, had not reached their present-day perfection, yet if Kearton's photographs be examined, some of them, even by present-day standards, are still well-nigh perfect, although almost half a century has passed since Kearton began his work.

Many persons, their enthusiasm fired by the early workers, have followed their example and have published their photographs in book form. The present book, by Eric J. Hosking and C. W. Newberry, is a comparatively small and unpretentious work, yet the photographs which illustrate it are in the very first class—I doubt whether anything better of their kind has been published. It is, perhaps, a pity that the identity of the photographers is not revealed beneath each picture. For example, one is left in the dark as to whether it was Mr. Hosking or Mr. Newberry who took those really beautiful photographs of the stone curlew at home, but it is perhaps to be inferred that the joint authors of the book worked together.

The letterpress of the book is inferior to the photographs, but there are recorded interesting first-hand observations—for example, the pied flycatchers of a valley of Wales began to nest only a few hours after their arrival at their summer haunt, and "the modern flash bulb, which gives a short flash without noise or smoke, has no disturbing effect on many wild birds, which apparently regard it as a natural phenomenon, perhaps akin to lightning" (p. 49). The authors also describe the excitement of a cock partridge, on being called to the nest by the hen, to see the first-born chick. On p. 40 is found what may be a very modest statement, "Our work was interrupted by an accident while working on a tawny owl". Can this have been the ferocious tawny owl which attacked Mr. Hosking and caused the loss of one of his eyes? Yet even after that, Mr. Hosking, although he says nothing of it in this book, refused to admit defeat, or to harbour ill-will against the owl, but continued to photograph it after a few days' rest. The series of woodcock photographs are particularly fine, and there is an excellent buzzard series.

The authors do their best to prove that the little owl is not the villain it is generally supposed to be, but there would seem to be a good deal of contrary evidence—witness the great destruction worked by a pair of little owls among the storm petrels of Skokholm. SETON GORDON.

THE CELL THEORY

Hundert Jahre Zellforschung

Von L. Aschoff, E. Küster, W. J. Schmidt. (Protoplasma-Monographien, Band 17.) Pp. x + 285. (Berlin: Gebrüder Borntraeger, 1938.) 16 gold marks.

BEFORE he can come near to understanding the complicated structures and immense variety of form encountered in the living world, the natural scientist has to reduce them to their simple ultimate components. These elementary units should be able to live by themselves, and also to combine with each other to produce more and more complex systems. The search for the fundamental unit of living matter was greatly influenced by the thought of Leibniz, while Brown, Bichat and Purkinje among others looked for such components. It was not, however, until Schleiden put forward his cell theory in 1839 that general agreement as to the nature of the elementary unit was reached. Schleiden's theory provided both a sound basis and a guiding principle for the study of the microscopic structure of plants, which were soon applied to normal animal tissue by Schwann, and to pathological material by Virchow. The cell theory thus gave a new and vigorous impetus to microscopic investigation, as well as leading to the development of specialized techniques.

Küster, Schmidt and Aschoff have taken the opportunity afforded by the centenary of the first enunciation of the cell theory to publish a little book in which they not only trace the broad outlines of the course and general results of cell research during the last hundred years, but also examine the validity of the cell theory in the light of our knowledge to-day. On reading this book one is not only impressed by the progress made in this field since 1839, but also by the amount which was known of the structure and function of cells before ever the cell theory was formulated.

As commonly understood, the cell theory contains two main statements: (1) that the cell is *the* elementary form of life, and (2) that every organism is composed of cells and cell derivatives. While the book under review contains an adequate summary of research done during the last hundred years, that part of the book concerned with the examination of the validity of the cell theory is rather disappointing, because of the authors' rather uncritical tendency to accept the traditional outlook. They agree that the first statement of the cell theory needs modification, since viruses cannot be regarded as cells, and that there must, therefore, be more elementary forms of life than the cell. Schmidt believes in various degrees of life and in the transition of the non-living into the living organization. Aschoff favours this conception, but does not reveal how he reconciles it with his acceptance of Virchow's law, *omnis cellula e cellula eiusdem generis*. All three authors accept the second contention of the theory, and believe that research during the last hundred years has not produced any results incompatible with it.

In considering the validity of the cell theory, one may perhaps ask whether the term 'cell' is sufficiently well defined. Most botanists, speaking of the cell, think mainly of the cellulose wall and its lignified derivatives, while the geneticist is concerned for the most part with the chromosomal structure, and the biochemist has in mind an aggregate of enzymes enclosed within a semi-permeable membrane. Thus the very meaning of the word 'cell' tends to vary with its context. Further, the character of every actually existing cell depends on the tissue and species of organism from which it is derived, and even in tissue culture cells retain these characteristics and do not become simple living elements. Thus it is impossible to conceive of the cell as a sort of chemical atom, an elementary unit of interchangeable qualities.

It is true that no understanding of structure and form in the living world is possible unless cellular organization is taken into account, but at the same time the reduction of an organism to a combination of similar elementary units is not sufficient to explain the differentiation and functional structure of the different organs and tissues involved. Consequently a number of new conceptions, such as the field theory put forward by Child, Heidenhain's *Teilkörper* theory and the theory of functional systems, are being tried to supplement the cell theory. Unfortunately, Aschoff dismisses all these attempts as being of no importance since they can be worked into the cell theory.

A. GLÜCKSMANN.

RELATIONSHIP OF CRIME AND INTELLIGENCE

Intelligence and Crime

A Study of Penitentiary and Reformatory Offenders. By Simon H. Tulchin. Pp. xiii+166. (Chicago: University of Chicago Press; London: Cambridge University Press, 1939.) 12*s*. net.

THIS investigation is primarily an inquiry into the relation between crime and intelligence. But the bearing upon crime of other variables such as age, height, weight, nativity, educational record and employment is also taken into account. The subjects are 4,748 males at the Illinois State Reformatory, 5,512 males at the Illinois State Penitentiary and 153 penitentiary females. The research was carried out over a period of seven years.

No doubt this is a very painstaking piece of work, but the results are presented more as raw material for further study than as data thoroughly analysed. Three criticisms, in particular, suggest themselves. First, the control groups are inadequate. Secondly, no tests of significance are applied to the large number of differences between means; nor is any analysis of variance attempted. The reader is thus left guessing how many of the observed discrepancies are attributable to chance. Thirdly, the grouping of the criminals into only seven types of crime is much too crude a classification for a thoroughgoing analysis. The seven types of crime are fraud, robbery, larceny, burglary, murder, sex, and a group described as miscellaneous.

In spite of these defects, the reader feels that certain important conclusions can be accepted. Serious doubt is thrown upon the traditional view of Goddard, Healy and others that there is an abnormally high percentage of feeble-minded among the criminal population. Tilchin shows, on the other hand, that the distribution of ability in his criminal subjects scarcely differs from the distribution in adequate samples from the general community in the United States as, for example, in the American Army samples. Moreover, as Murchison had found earlier, the ability of the offender is definitely related to the type of crime he will commit. The fraudulent are generally the most able. Age and height are also relevant factors in determining types of crime. Finally, scores on the tests used, far from measuring 'innate' ability, correlate significantly with environmental factors such as place of birth, length of residence in a particular region, and educational level.

J. I. COHEN.

AN EAST AFRICAN PEOPLE

The Social Institutions of the Kipsigis
By Dr. J. G. Peristiany. Pp. xxxiv+288+24 plates. (London: George Routledge and Sons, Ltd., 1939.) 18*s*. net.

THE Kipsigis, better known among Europeans and to an earlier generation of anthropologists as the Lumbwa, are numerically the most considerable group of Nilotic Hamites in Kenya, their nearest affinities being the Nandi, Suk, Kamasia and Turkana. With the Masai they have a traditional enmity, which they trace back to the time of their first entry into the country they now occupy. This migration, it is to be presumed, was from the north.

The literature relating to the Kipsigis, though not entirely lacking, is scanty, and from the point of view of modern anthropological method, partial and inadequate. This is the further to be regretted, since the recorded observations of the related peoples, Nandi and Suk, dating for the most part from the first decade of the present century, are both scrappy and self-contradictory. It is pointed out by Dr. E. E. Evans-Pritchard in his interesting introductory analysis of Dr. Peristiany's material to what an extent these present observations among a closely related people serve to throw light on previous obscurities in these early records. In this connexion it may be mentioned as significant of the degree of inter-tribal relation that a Kipsigis crossing into Nandiland fits into the age-set corresponding with his own, and is at once accepted as a member of it.

The social organization of the Kipsigis is of a highly complex character. The fundamental system is local. The basic unit is the village, built up from family holding and hamlet. The villages in their turn combine to form the shire, and the shires the higher unit of the province, four of which constitute the Kipsigis tribe or nation. There are no chiefs, but in each grouping, political and juridical, military and ritualistic leaders regulate the departmental affairs of the group, with the assistance of the elders, who virtually control the action of the leaders and give effect to the democratic character of Kipsigis institutions. Economic affairs stand outside this hierarchy of leadership. Here the village organization with its economic leader is the effective unit standing alone, its special function being that of facilitating and ensuring co-operation between its members. So deeply engrained is this principle of co-operation on a local basis, that assistance will be tendered to a neighbour in preference to a distant kinsman.

The complexity in a social system thus built up upon a gradation of locally organized units is intensified by other methods and systems of classification of overriding significance, which cut across local organization. Among these may be mentioned the regimental system for raiding purposes, under which each individual is born into a regiment, although it is possible to be designated to an alternative—but in either event the regimental affiliation is independent of territorial claims; the age-set, by which the whole community, including in so far as applicable the women, is divided up into three age groups of the young or uninitiated, the warriors, and the elders; and the clan system, based upon totemic non-exogamous groups, subdivided into exogamous branches, each with its distinctive totem, from which the members take their name, these sometimes being still further subdivided, the exogamous unit then becoming the lower division.

The various affiliations of which the individual is the centre or focus tend to eliminate the parochialism which might, or indeed would inevitably, result from a purely local system, and bind the Kipsigis into one people. This effect is enhanced by other institutions, such as for example the practice followed by wealthier individuals of planting out the homesteads of their various wives in different parts of the country, or depositing a number of their cattle in the keeping of friends and connexions. As to how far it would be safe to attribute outstanding importance to any one influence on the life of the individual it is difficult to say; but just as initiation, which admits to the warrior age-set, is the outstanding event of a lifetime, so the age-set, which determines the character of the social activities of every member of the community, would seem to overshadow all other affiliations. Dr. Peristiany not only gives a detailed account of the elaborate initiation ceremonies, but also discusses their place in the regulation of tribal life and conduct, while touching upon the effect of certain changes which have taken place in them in recent years.

Following on his account of this complex social organization, Dr. Peristiany has described with a wealth of detail its various ramifications and its effect on the family—marriage, economic life, inheritance and property, war, hunting, religion and other departmental institutions in the community. His scholarly study is a valuable addition to the literature relating to the less familiar peoples of East Africa.

PREVENTION OF MALARIA IN INDIA

RECENT ADVANCES

By Sir Malcolm Watson,

Director, Ross Institute of Tropical Hygiene

ALTHOUGH the primary object of my recent visit to India was to see what progress had been made in preventing malaria on estates advised by the India Branch of the Ross Institute, I took the opportunity of visiting Delhi and Hyderabad, Deccan. In all these areas astonishing progress has been made since my visit in 1928–1929.

For more than a thousand years there has been a succession of cities on the western bank of the River Jumna within six miles of new Imperial Delhi. Some of the cities were far enough from the river to escape the malarial mosquitoes which breed in pools in its bed. But three hundred years ago Shah Jehan made the mistake of building his city right on the river bank; the Western Jumna Canal irrigated its northern area; the Darhalia Nala flowed through the western suburb. In all three, *Anopheles culicifacies* bred in profusion; and at times Shahjehanabad was the most malarial military station in India. In 1903 the General Officer commanding the Division commented on "the havoc caused in the Delhi Fort garrison". Of the relieved force, 315 per 1,000 were unable to march back to Meerut, and of the remainder quite one fourth were scarcely fit to carry arms. A few years later the cantonment of Daryaganj in the south-east corner of the Fort and immediately on the Jumna was abandoned on account of malaria. New Delhi, built not quite so near to the river as its immediate predecessor, provided accommodation for myriads of *A. culicifacies* in the four hundred miles of margins of concrete tanks which adorn the new capital. Further accommodation for the anopheles was provided in pits in two hundred acres of brickfields and in innumerable artificial obstructions to natural drainage channels.

To-day a five years programme for the control of malaria is well advanced. It covers the eight miles of river bank and the various streams and canals falling into the river, the irrigated area, the brickfields and much besides: good sound work that is producing the required result. Indeed, Daryaganj, the abandoned, is now being developed as a residential area.

Not less interesting, and of great importance to India, is the control of malaria in sixty-six villages within three miles of the city, and in sixty villages farther afield. The work is being done after careful study of the habits of the dangerous anopheles, *A. culicifacies*. Depressions have been filled, and the land sloped to run all surface water to one or more of the village tanks, where any mosquitoes that breed can easily be destroyed. While concentrating on the prevention of malaria, water supplies have been improved, and the general cleanliness of the villages has not been neglected. The co-operation of the villagers has been secured. The anti-malarial work at Delhi is under Lieut.-Colonel Covell, director of the Malaria Institute of India. It costs money—often much money—to repair mistakes that could have been avoided in the original work without additional expense. Now co-operation between the various authorities prevents more man-made malaria, and I was impressed by the economy and efficiency of the work.

The prevention of malaria by the Government of India has not been confined to Delhi Province. The Government of H.E.H. the Nizam has reduced the percentage of children suffering from malaria in the old city of Hyderabad (one of the worst areas) from 55 to 0·5; a suburb of the city, falling into decay in 1929, is now thriving and land values have risen; a completely new suburb has been built on land previously regarded as uninhabitable. Twenty years ago there were 16,000 deaths a year from plague, now there are 100 or less. Slum clearance proceeds rapidly, and there are many attractive rehousing schemes. Some of the small houses, the economic rent of which would be Rs. 3 a month, are let at Rs. 1 a month to those who abjure alcohol. These houses have pillars shaped like inverted tumblers —a reminder of the pledge. Improvements in many other ways have been made, and with its progressive Government Hyderabad is becoming a model Indian city; nor have the improvements been confined to the capital of the State.

For more than two months I toured estates in southern India; the Surma and Assam valleys; and the Dooars, an area under the shadow of the Himalayas. In many of these districts malaria had been intense and blackwater a too frequent visitant. Since I made much the same tour eleven years ago a great change has occurred. Almost everywhere on the estates the prevention of malaria is in active progress. Confidence has replaced pessimism; on many estates managers, assistants and medical officers are full of enthusiasm at the wonderful results achieved. Although I made constant inquiry I heard of no case of blackwater fever in a European in the last two years.

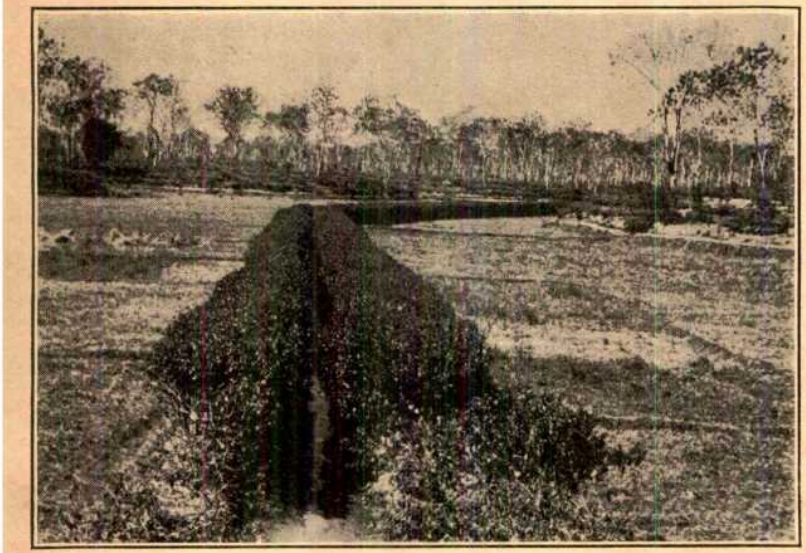
Sixteen years ago, when I spent three months in Assam on the invitation of the directors of the Doom Dooma and its associated companies, the control of malaria by controlling mosquitoes was regarded as impossible. The Assam Valley, or syncline between the Himalayas and the Burma Hills, three hundred miles long and fifty miles wide, is, I am told, filled with detritus from the hills to a depth of three miles. To the eye it appears a level plain, and it well might as it was formerly an arm of the sea; even now the Brahmaputra River is navigable almost the whole length of the valley throughout the year. In the spring the melting snows of the Himalayas and vast areas of Tibet make it one of the mighty rivers of the world, five to seven miles wide. Its waters flood back into the local rivers, mere tributaries of the Brahmaputra, but some wider than the Thames at Westminster. Then with scarcely an interval come the monsoon rains—80–120 inches in less than six months. Hundreds of square miles disappear under water; for wherever possible water is stored by the Assamese, whose staple food, rice, is grown in sheets of standing water. Can we wonder that more than twenty species of anopheles have found the valley a happy home, or that to the earlier investigators the malarial problem of controlling mosquitoes seemed insoluble?

My researches in Assam, and more than twenty years experience of Malaya, led me to take another view. Between 1900 and 1910 the combination of research and practical work in Malaya showed the openings in the mosquitoes' armour. The work had included, in addition to laboratory work, large-scale experiments in which miles and years took the place of millimetres and minutes; for the malaria problem could not, in the end, be brought within the four walls of any laboratory. We had learned that, although there were many species of anopheles all of which could be artificially infected in a laboratory, few became infected when wild, and happily few areas had more than one dangerous species; that to control malaria we had to control only the dangerous species; that the larvæ of the different species lived under different conditions of light and shade, of stagnation or movement of water; that changes in these conditions or in the chemical composition of the water would change the species present; and that a method of control 100 per cent successful against one species might be worse than a failure against another species. For example, *A. maculatus*, the larvæ of which live in hill streams, sparkling in the sunshine, required very different measures of control from *A. umbrosus*, an inhabitant of jungle-covered stagnant swamps. So came about what is known to-day as 'species sanitation'; and in 1910, at a public lecture, I stated that following the methods of limiting and changing species shown to us by Nature, "a great anti-malarial method will be evolved . . . we shall be able to play with species of anophelines, say to some 'go' and to others 'come', and abolish malaria with great ease, perhaps at hardly any expense. Drainage may become a method of the past. . . ." In addition to other methods of malaria control like site selection and oiling, Nature's methods are widely employed on estates in India to-day.

Dr. G. C. Ramsay followed up my researches in India. He proved *A. minimus* to be the only important carrier of malaria on the estates in his practice, and went on to control it. In 1930 he was appointed head of the India Branch of the Ross Institute. His scheme of training young Indians has been expanded by Dr. Manson, Dr. Fraser and other medical officers co-operating with the Ross Institute, and to-day more than five hundred trained Indians are employed on estates to identify the species of anopheles caught, to dissect them to see if they are infected with malaria, to collect anopheles larvæ and prepare maps showing the breeding places of the different species. Small field research stations have been temporarily opened in different parts of India from Cape Comorin to the Himalayas, from Sind to Assam. More than two hundred thousand anopheles have been dissected and several species have been convicted of carrying malaria. There are now one or two permanent training centres to meet the demand for trained malarial surveyors—a new and useful form of employment for the educated Indian fresh from school.

To control the different species of anopheles appropriate methods are employed. A description of some of them would be strange reading for those who were taught only of the danger of jungle, of stagnant water, and swamps, and have not been initiated into the secrets and mysteries of modern malaria control.

For example, on many estates in India, as in Delhi, much malaria has been 'man-made'. Over wide areas of both northern and southern India, the malaria is entirely due to man interfering with Nature by his clearing away jungle from streams and exposing them to the sunshine, and by his draining swamps. For by doing so he has driven out the jungle-loving or harmless species and permitted the breeding of dangerous species—*A. minimus* in the north, *A. fluviatilis* or *A. culcifacies* at different elevations in the south. Intermittent flushing will wreck the home of even the fastest stream-breeding malaria-carrier in the world; it is much used in India. Streams are flushed by hand-operated openings in simple earth dams; by automatic tippers, costing a shilling or less, of a design that would rejoice the heart of Mr. Heath Robinson; or by more elaborate things of concrete and iron. In other places, if man holds his hand, Nature will cover up her wounds with secondary jungle, but often she is too slow and we must replant appropriate shade. So we see the strange sight of hundreds of acres of little squares of almost stagnant water growing rice in the sunshine, and down the centre of the rice fields a stream densely shaded by a hedge; it may be of the lovely shoe flower (Hibiscus), the wild rhododendron (Melastoma), the notorious Lantana or other plants. The centre stream alone was the danger. The hedge has made it harmless, and an intense source of malaria has been eliminated. The accompanying photograph shows a rice field in the dry weather with the hedge pruned to make the shade denser in the rainy malarial season. There are 2,000 miles of these dense hedges now, and 4,000 miles will be effective by the end of the year.



ANTI-MALARIAL HEDGE IN A RICE FIELD (PRUNED IN NON-MALARIAL SEASON).

Progress has not been confined to the prevention of malaria. I was astonished to see the general improvement in the water supplies, in latrine accommodation, in refuse collection and disposal, in housing of the labourers, in the hospital buildings and the high standard of medical work in so many of them, the care of the sick and the ante-natal work.

From a commercial point of view, a remark made by the head of one of the largest tea-producing concerns in India represents the general opinion: "We have gone carefully into the figures and are convinced of the value of malaria control"; and he added, "in fact we have some of the finest examples of the control of malaria both in north and south India", for the truth of which remark I can vouch. The following are figures from one group of estates, representative of many:

	1927 Before control	1938 After 10 years control
Population	17,770	18,670
Death-rate per 1,000	31·5	21·4
Total 'sick' days	249,306	147,993
Children with malaria (spleen-rate)	60%	14·3%

To the employer these figures mean a lower sick-rate, a lower death-rate, greater efficiency in his labour force and lower cost of production. To the labourer they mean healthier and happier homes and a higher pay packet at the end of the month: 100,000 more days pay than ten years ago, on this particular group of estates. Until the new standardized returns come into general use, we shall not be able to compute the total benefit to the Indian labourer on estates; even now we can think, without the least fear of exaggeration, in terms of a gain of more than a million days wages a year.

This work has not been confined to the European-owned estates. Already several Indian-owned and Indian-managed estates have joined the local Ross Institute centres, and the Governments of Assam and Madras are co-operating with the estates to improve the health of several villages. The hope has been expressed that the European estates with their trained staffs will assist their Indian neighbours to control malaria and other diseases, to the advantage of both and the removal of what is at present a source of friction.

On Dr. G. C. Ramsay, deputy director of the Ross Institute, has fallen the heat and burden of the day. He has succeeded only because of the fine co-operation of his medical colleagues and the planters and of the support of the directors in India and at home. Sometimes the question is asked: "Can any good [medical] thing come out of Britain"? So perhaps I may be excused for expressing the opinion that the work in India is the greatest achievement in the control of malaria in the past decade; that the best of it, and there is much 'best', is worthy of comparison with the best work done at Panama or with Mussolini's great achievement in the Pontine Marshes; and in area it is vastly greater than either. Moreover, both could learn something to their advantage from India. Nor is this the whole story; for Ceylon, certain areas in British Africa, and Malaya have also fine records in preventing malaria—in Malaya begun even before Panama.

This story would not be complete without mention of how this work was made possible. The late Sir Charles McLeod, first chairman of the Ross Institute, who used to insist that "malaria, malaria" was the great enemy, and a number of his friends in the City financed the India Branch of the Ross Institute during 1930–1933, when the responsibility was taken over by the Indian Tea Association.

During this tour I visited the humble laboratory at Hyderabad in which Ronald Ross made his immortal discovery. Often I wished he could have been with me to see how mosquito reduction had spread still farther into rural areas, which as he wrote to me in 1909 he had "never dared to moot".

THE CORROSION OF FERROUS METALS

By Dr. J. Newton Friend,
Central Technical College, Birmingham

In 1916 a committee was formed by the Institution of Civil Engineers, under the chairmanship of the late Sir William Matthews, to investigate the "Deterioration of Structures exposed to Sea Action". The Department of Scientific and Industrial Research gave every encouragement and offered substantial financial assistance.

An important section of the work undertaken by the Committee is that dealing with the corrosion of iron and steel. This research has now been completed. Series of bars of fourteen different kinds of ferrous metal, measuring 2 feet in length, 3 inches in width and 0·5 inch in thickness, were exposed at various ports to sea air, to alternate sea air and wetting with sea water or spray, and to continuous immersion in the sea. Three sets were exposed at each port to each of these conditions, one for five years, one for ten and the third for fifteen years. The results obtained with the five and ten year bars have already been fully discussed in the Committee's Fifteenth Report (1935). As yet only the numerical data for the fifteen-year bars have been made public in the Committee's Seventh Interim Report (1938), the full report being temporarily held up on account of the War. It may be said at once that these last results support the earlier ones very satisfactorily, and it is the purpose of this article to mention a few of the more important practical conclusions to be derived from the numerous data now published.

The ports chosen for the exposure of the bars were Auckland (New Zealand), Halifax (Canada), Plymouth (England), and Colombo (Ceylon). These were selected as offering a wide variation in climatic conditions. Thus Colombo has a moist, tropical climate, and the total loss in weight suffered by the bars through corrosion at this port was twice that experienced at Plymouth, three times that at Halifax and nearly four times that at Auckland. Nevertheless, the relative losses among comparable sets of bars were quite analogous and thus enable us to draw many useful conclusions with a high degree of confidence.

The severe nature of the corrosion at Colombo is illustrated in Fig. 1. The steel bar *B*14 was perforated near its middle after exposure at half-tide level for ten years, whilst, after fifteen years exposure under similar conditions, bar *E*15, also of mild steel, was completely eaten in two.

At Plymouth three sets of bars were exposed to fresh-water action by immersion in the reservoir at Turnchapel for the above-mentioned periods.

In all cases the bars were maintained in a vertical position by embedding their ends in concrete, which was carefully punned into position so that no air holes or porous sections were left around the metals. The concrete proved an ideal material for the purpose. After fifteen years exposure the metal beneath the concrete was in perfect condition, except in a few cases where the concrete had cracked from one cause or another.

Moist concrete is not a perfect insulator, particularly when impregnated with salt water. Experiments carried out at Plymouth showed that minute electric currents undoubtedly passed through the frames when immersed in the sea. Hence a small amount of electrolytic corrosion was induced in some of the specimens. Most fortunately, measurement showed that this was too small to affect seriously the results, owing to the relatively great distance between the experimental bars and the re-inforcing steel rods. Had the specimens been placed appreciably closer either to one another or to the tie-bars, the effect might have been serious. This is a point worth noting in future investigations; it does not appear to have been considered hitherto.

The metals selected for study comprised: (i) three rolled irons, namely, Low Moor, Swedish and ingot irons; (ii) four carbon steels, with carbon ranging from 0·2 to 0·4 per cent; (iii) five alloy steels containing respectively 0·6 and 2·2 per cent copper; 13·6 per cent chromium; 3·75 and 36·6 per cent nickel; (iv) two cast irons, exposed in their 'skins', namely, hot blast metal *Q* and cold blast metal *R*.

In an exceptionally well-illustrated paper, read before the Institution of Civil Engineers on April 4, 1922, Sir Robert Hadfield gave a detailed account of the preparation, analysis and mechanical testing of these bars. This paper was briefly summarized in NATURE of December 30 of the same year.

As was to be expected, the high nickel steel proved, on the average, the most resistant to all forms of attack. But its high cost and special mechanical properties obviously militate against its general adoption. The chromium steel behaved remarkably well in air and in fresh-water, but in contact with sea-water it suffered such severe localized corrosion as to render it useless.

The cast irons stood up well against aerial corrosion, the cold blast metal proving slightly the more resistant. In contact with water, however, particularly sea-water, graphitization took place, sometimes working its way so deeply into the bar as to leave only a thin core of unattacked metal. This is well illustrated in Fig. 2; bars *Q*11 and *R*11, exposed to sea air at Colombo for ten years, yielded practically perfect fractures. The fractures of the other bars, exposed at half-tide level and to complete immersion in the sea, show how deeply graphitization had penetrated. The corrosion product was hard and so firmly attached to the core that it seemed impossible to remove it by mere mechanical means. Indeed, in some cases it was not until the bars had been intentionally fractured that it was realized how seriously the cast iron had been attacked. The general appearance of the bars was most misleading and, in view of this, cast iron cannot be recommended for purposes other than aerial.

In the aerial tests, Low Moor iron was found to corrode more seriously than mild steel; in fresh-water the two metals behaved pretty much alike; at half-tide level the wrought iron was slightly superior, and when exposed to complete immersion in the sea the wrought iron was decidedly superior. An answer is thus afforded to the vexed question of iron *versus* steel, in that it is shown to depend upon the type of corrosion to which the metal is destined to be exposed. Mere averaging makes the two metals appear to behave alike.

The foregoing observations clearly prove that if we wish to know which particular metal to choose as most suitable for resisting corrosion, the particular type of corrosion must be specified. No metal is equally resistant to all types of corrosion, and so-called acceleration tests, carried out under conditions different from those to which the metal is destined to be exposed, may easily yield most misleading results. I had already pointed this out in 1911 in my book "The Corrosion of Iron and Steel" (Longmans), p. 276, and the conclusion arrived at then now receives overwhelming support.

An interesting feature of the research is afforded by the various ways in which the different metals have been attacked under the different conditions of exposure. Thus, for example, the surfaces of most of the bars exposed to sea air alone were covered with innumerable *pocks* of varying degrees of fineness or coarseness according to circumstances. The wrought irons exposed to sea-water were usually covered with furrows or narrow channels running down the full length of the bar, that is, in the direction of rolling. The appearance was

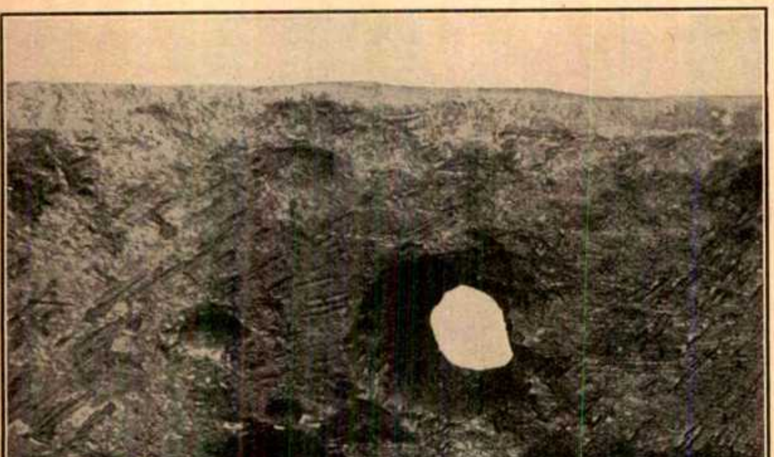


Fig. 1.

MILD STEEL BAR EXPOSED FOR TEN YEARS AT HALF-TIDE LEVEL AT COLOMBO.

characteristic and a mere glance enabled one to distinguish between the wrought irons and steels.

Whilst the wrought irons had been exposed in a cleaned condition, that is, ground free from scale, some of the carbon steels had likewise been cleaned, whereas others were exposed with their mill scale still adherent. It is instructive to contrast the behaviour of the steels under these two conditions. The following case is typical. Two mild steel bars, *A* 18 and *E* 18, of the same metal were exposed to complete immersion in the sea at Colombo for fifteen years. Bar *A* 18, which had been cleaned before exposure, was fairly uniformly attacked and its surface relatively smooth. Bar *E* 18 had been exposed with adherent scale, some of which could still be seen clinging to the metal. But where the scale had broken away, serious localized corrosion had occurred, analogous to that on *B* 14 (Fig. 1). Some of the pits penetrated more than halfway through the bar. Had two such pits happened to coincide on opposite sides of the bar, as did occur with *B* 14, the bar would have been perforated and virtually destroyed. The two bars had lost practically the same amounts in weight. Clearly it is most desirable to remove scale from steels destined to be exposed to sea action.

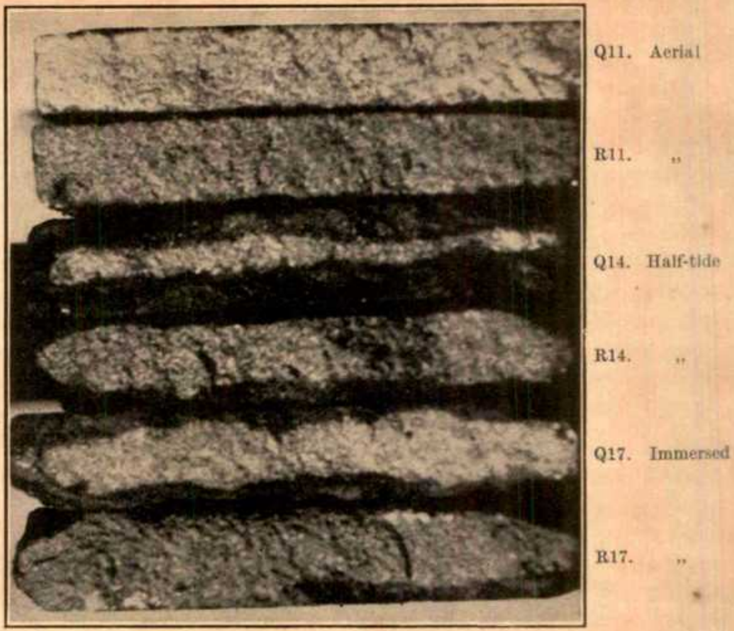

Fig. 2.

CAST IRON BARS EXPOSED FOR TEN YEARS AT COLOMBO.
Q = HOT BLAST; R = COLD BLAST.

In the case of the bars merely exposed to sea air, it was noted that the cleaned bars usually lost appreciably *less* in weight than the others—a result that was not expected. The differences in the depths of pitting were less pronounced, it is true, but such advantage as did occur lay again in favour of the cleaned bars.

The general progress of the corrosion of many of the bars exposed at half-tide level and to complete immersion in the sea was often rendered more complex by the presence of shelly fauna. Isolated shelly growths appeared to stimulate corrosion much in the same way as isolated patches of scale. Dead shell-fish seemed particularly deleterious, probably owing to the chemical activity of the organic decomposition products. At Auckland the bars were covered with a thick layer of shelly fauna which appeared to exert a mechanical protective action on the underlying metal. The fauna consisted mainly of barnacles and oysters; the former covered the bars whilst the oysters rested on top of the barnacles. In one case only was an oyster found to be in direct contact with the metal, and the position it had occupied was faintly discernible, after cleaning, as a slight depression on the steel.

Turning now to the alloy steels, it may be mentioned that the presence of 0·6 per cent copper greatly enhanced the resistance of the steel to sea air and to fresh-water. In contact with sea-water, the effect either way was small. Increasing the percentage of copper to two did not, in general, effect much improvement; indeed, in some cases it seemed disadvantageous. Any added cost thereby entailed would certainly not be justified.

The addition of 3·75 per cent of nickel effected a very great reduction in the corrosion of the bars exposed either to sea air alone or to fresh-water. At half-tide level and when completely immersed in sea-water, the nickel steel still proved superior to the copper steel, but less markedly so.

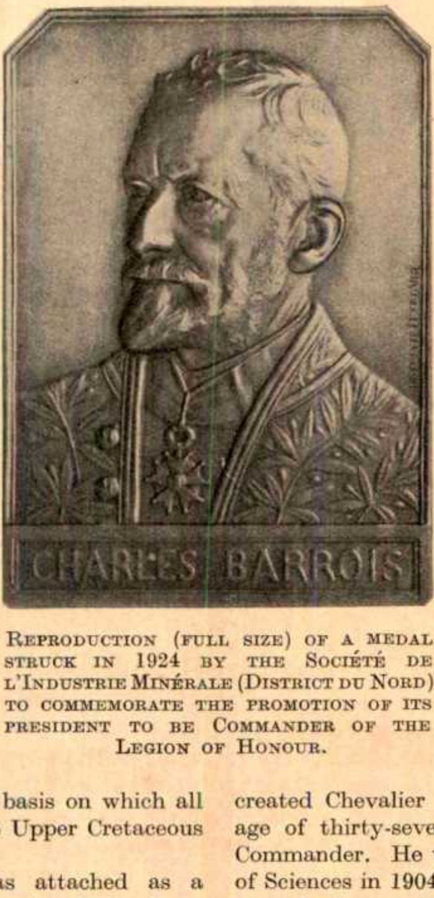
One point in connexion with the alloy steels would appear to be important, namely, that in general they show a greater tendency to localized corrosion or pitting than do ordinary carbon steels in contact with sea-water. Mention has already been made of the severe localized corrosion suffered by the chromium steel.

The full report of the Committee, when published, will contain valuable material. In a brief summary such as this, it is obviously possible to deal with only a few of the interesting results obtained. The present chairman of the Committee is Mr. W. T. Halcrow, and it is to be sincerely hoped that this valuable work may be continued as soon as circumstances permit.

OBITUARIES

Prof. Charles Barrois, For.Mem.R.S.

Among French geologists whose names are well known in England, that of Charles Barrois stands high with those of the great pioneers and leaders of geology which France has produced. For this there are many reasons, for not only were his scientific attainments of the highest order, but also he was always a staunch Anglophile and he had made himself known in his early days by his outstanding work in England itself.



Reproduction (full size) of a medal struck in 1924 by the Société de l'Industrie Minérale (District du Nord) to commemorate the promotion of its president to be Commander of the Legion of Honour.

Charles Barrois was the son of one of the great industrial families of the north of France, and it was natural that he should continue in the family business. As a young man he had always taken a great interest in geology, and when he came to England to study English methods of manufacture and become a fluent linguist, he found that his interests lay much more in geology than in the mills, with the result that he spent all his spare time studying his hobby.

About this time, at the age of twenty, Barrois decided to devote himself to science, and in 1871 he joined Prof. Jules Gosselet at the University of Lille in the newly formed Geological Department. Five years later he was granted a doctorate of science at the Sorbonne for his work on the Upper Cretaceous strata of England and Ireland. In this great work he showed that the palæontological zones recently established in France could be applied equally well in Britain. This work forms the basis on which all the subsequent zonal work on the Upper Cretaceous in Britain has been built.

About this time, Barrois was attached as a *collaborateur principal* to the Service de la Carte Géologique. The area which fell to him to investigate was the highly complex area of the Armorican Massif. His name appears on many of the sheets of the geological maps of Normandy and Brittany. Besides the maps themselves he wrote numerous papers, some descriptive and some of considerable theoretical importance, based on his studies of this highly complex area. Although essentially a stratigrapher, he wrote on such problems as the emplacement of granites and general petrographical problems. In the later years of his life he frequently returned to this area to revise his earlier maps.

It is natural that since his university was in the neighbourhood of the coalfields of the Nord and Pas-de-Calais, Barrois should have joined Gosselet in applying his geological knowledge to the problems of that complex field. As knowledge accumulated and the correlation of the various beds and seams was established, the structure of the field was elucidated. These studies led to the founding of the Musée houiller de l'Université de Lille in 1908, with models of many of the chief collieries made on plates of glass giving a wonderful three-dimensional picture of the extraordinary complex structures revealed in the process of mining.

In 1919, Barrois, with Prof. P. Pruvost, his pupil and successor to the chair of geology at Lille, carried the knowledge learned in the north of France to a study of the coalfields of Lorraine and the Sarre. In 1902 he succeeded Gosselet as head of the Geological Department.

Besides the work in France and England, Barrois worked in Spain and was a well-known member of numerous geological excursions and congresses in many parts of the world.

During the War of 1914–18, Barrois felt it his duty to remain with his collections in Lille and spent four years there under the German occupation. During this period his old master, Gosselet, died; now again under the shadow of war, Lille has lost another of its great geologists.

Prof. Barrois received many honours. In France he was created Chevalier of the Legion of Honour at the age of thirty-seven and in 1923 was promoted to Commander. He was elected to the Paris Academy of Sciences in 1904 and became its president in 1927. Outside France he was also honoured; he was a foreign member of the Royal Societies of London and Edinburgh, and he was senior foreign fellow of the Geological Society of London, receiving its highest award, the Wollaston Medal, in 1901. He was foreign member of many societies and academies, of the United States, Belgium, Spain and Germany, and he was also a member of the Pontifical Academy.

Barrois died at the age of ninety-one on November 5, 1939, in Normandy, but was buried at Lille, where the funeral service, conducted by the Cardinal Archbishop of Lille, was held in his parish church of Saint-Maurice-des-champs, a suburb of Lille.

The Rev. F. C. R. Jourdain

THE death of the Rev. F. C. R. Jourdain at his home in Southbourne, Bournemouth, on February 27 at the age of seventy-four is a grievous loss to European ornithology. Jourdain was generally recognized as the leading authority on the breeding biology of the birds of the Palæarctic region, and the accuracy and comprehensiveness of his knowledge of the subject has not been equalled by any ornithologist past or present. His great collection of the eggs of Palæarctic birds was formed in a truly scientific spirit unfortunately too rare among collectors of eggs, and its value for comparative purposes is unrivalled, so that it is greatly to be hoped that it may be preserved intact. But although Jourdain was an enthusiastic collector, he was intensely interested in every aspect of the breeding biology of birds, and his mastery of his subject was based on a happy combination of wide field experience and an encyclopædic knowledge of the literature. For many years he had made a collecting expedition almost annually, visiting in this way almost all of the more ornithologically interesting parts of Europe (excluding Russia) and North Africa, and these trips resulted in a number of valuable faunistic papers in the *Ibis* and elsewhere.

Jourdain tabulated and classified with amazing industry the whole mass of data on the breeding of Palæarctic birds from the extensive literature, supplemented by his own experience and that of a wide circle of correspondents, and his sections on breeding habits in the "Handbook of British Birds", now appearing, are marvels of concise and exact information which could have been written by no other ornithologist. Moreover, the enormous increase in detailed knowledge of the subject recorded in the "Handbook" as compared with its smaller predecessor, the "Practical Handbook of British Birds" (1919–23) is in very large measure directly due to the stimulus given to further investigation by his orderly systematization of the facts then known in the older work. He was also responsible for the sections on food, distribution abroad, and (jointly with me) on display. It is sad that he did not live to see the completion of this crowning achievement of his life's work in ornithology; but it is gratifying to know that his sections in the final volume will be completed mainly from his own comprehensive notes. References to the various other standard works on British ornithology in which he collaborated and to his many notes and papers on British birds will be found in the longer notices in *British Birds* or the *Ibis*.

Jourdain was an unsparing critic of inaccuracy in matters of fact with regard to birds, or support of theories which he believed to be contrary to the evidence, and his frequently witty, but withering style in controversy made him enemies in some quarters. This fighting trait was very characteristic, but the reputation which it gained him gave many a quite wrong impression of his real character. This was much more truly displayed in his unfailing willingness to assist and advise every serious student of birds who asked for his help, and above all in his constant and generous encouragement of the younger generation of ornithologists, which found full scope in the years following the War of 1914–18, when he was rector of Appleton, near Oxford. The prominent part played by Oxford in recent years in the organized study of the bionomics of birds, now centred in the Edward Grey Institute of Field Ornithology, may be traced directly to his influence, and this is not the least of his contributions to the scientific study of birds to which he devoted his life.

B. W. TUCKER.

Mr. E. E. M. Joyce

ERNEST E. MILLS JOYCE, who died on May 2 at the age of sixty-five, was one of the remarkable group of naval ratings chosen by Captain Scott for the National Antarctic Expedition of 1901, and his name will live with those of Frank Wild and Edgar Evans among the sailor explorers of his time.

On the *Discovery* expedition Joyce developed qualities of independence and self-reliance which led Sir Ernest Shackleton to persuade him to leave the Navy, where he was a chief petty officer, and to join the *Nimrod* expedition of 1907. To him Shackleton confided the responsible task of laying out the depot at the Bluff in a fixed position, with provisions for the last lap of the homeward journey. This was done after Shackleton's departure on his great southern journey, and the success of the return journey was due to the perfect performance of this duty. During the winter of waiting at the base Joyce became skilled as a printer and he produced "Aurora Australis", the only book ever printed and bound in the Antarctic regions. This book is now one of the rarest finds for any collector.

Joyce was employed by Sir Douglas Mawson when equipping the *Aurora* expedition in 1912 to select Greenland dogs in Denmark and convey them to Tasmania. He remained in Australia until 1914, when Shackleton called on him to undertake the transport arrangements of the Ross Sea branch of that Imperial Trans-Antarctic Expedition which he had planned in a too optimistic spirit. The *Aurora*, under the command of Captain Aeneas Mackintosh, took the party to Macmurdo Sound, in order to lay out a line of depots as far as the Beardmore Glacier with supplies for Shackleton and his party, who were expected to cross the Antarctic plateau from the Weddell Sea by way of the South Pole. The captain, who was in charge, and other members of the sledge party were overcome by scurvy on the way to the Beardmore Glacier, and Joyce assumed command. The sick men had to be carried on the sledges during the return and one died; but Joyce, under tremendous difficulties, laid out the depots exactly as planned, and if Shackleton had been able to land in the Weddell Sea he would have found his last stage easy. Joyce's enormous strength and ruthless determination enabled him to achieve this feat and to bring all but one of his party safely to the advanced base. He has given a grim but vivid description of this terrible journey in his "South Polar Trial", published in 1929.

HUGH ROBERT MILL.

Prof. Edoardo Maragliano

PROF. EDOARDO MARAGLIANO, the famous Italian physician, whose death recently occurred in his ninety-first year, was born at Genoa on June 1, 1849. He received his medical education at Naples, where his principal teachers were Salvatore Tommasi and Arnaldo Cantani, and qualified in 1870 with a thesis "of exceptional merit" on some diseases of the nerve centres. He started his career by being assistant to Prof. Enrico de Renzi at Naples for a few years, and then became lecturer in general pathology at Genoa from 1877 to 1881. He was then elected professor of clinical medicine at Genoa, and held this post for forty-three years.

Maragliano succeeded in making his clinic at Genoa one of the most celebrated in Italy, and it was attended by practitioners from all parts of the country and abroad. Though he always subordinated laboratory examinations to clinical observation, he established a number of laboratories in connexion with his clinic to deal with the various problems connected with clinical medicine. His excellence as a teacher is shown by the fact that eight of his pupils afterwards obtained professorial chairs in various Italian universities.

Maragliano's writings ranged over all fields of internal medicine, including pneumococcal infections, cholera, and disorders of the blood and heart, but the disease in which he was most interested was pulmonary tuberculosis, and particularly prevention of the disease by a vaccine containing dead bacilli. Although the value of this method has not been proved, he did good work in conducting an active campaign against tuberculosis in Italy and he was largely responsible for a decline in its prevalence.

For seven years Maragliano was president of the Medical Faculty of Genoa and for more than ten years rector. In 1900 he was elected senator of Italy. His other activities consisted in the foundation of the Genoa Academy and an Italian Society of Internal Medicine in conjunction with Cantani and Bacelli, as well as of a post-graduate school for tuberculosis at Genoa which was attended by numerous practitioners from all parts of Italy. He was also founder of *Archivio Italiano di Clinica Medica* (1893), *Annali dell' Instituto Maragliano per lo Studio e la Cura della Tubercolosi* (1904) and *Archivi di Biologia* (1924). During the War of 1914–18, in which he was given the rank of major-general, he was appointed director of the military clinic at Padua.

J. D. ROLLESTON.

Mr. W. S. Furneaux

MANY a school-boy of forty years ago and many younger school-boys and former pupils will be sorry to hear of the death of W. S. Furneaux. He had the knack of writing just the sort of succinct and well-illustrated practical book which stimulated the young collector to hunt for spoils and afterwards to pore over the naming of them; and his publishers aided and abetted with that profusion of coloured plates which added attractiveness to utility. "The Outdoor World" (1893), one of the best of the series, was followed by accounts of "Life in Ponds and Streams" (1896), "The Sea Shore" (1903), and "Field and Woodland Plants" (1909), and these and his other works, such as "British Butterflies and Moths" (1894), must have opened up new worlds for young naturalists of two generations. It says something for their quality that they are still amongst the best of British books for their purpose.

Furneaux was born at Devonport in 1855, and was educated at Cheltenham College. Eventually he came to London, where he taught science successfully and with appreciation for many years, first as lecturer at the Pupil Teachers' Training Centre and principal of the Science and Art Evening Institute at Peckham, and later as lecturer in the Teachers' Day Training College at Islington. He retired in 1913 and settled in Felbridge, Sussex, and there his own love of Nature was exercised in the skilful and enthusiastic way in which during the course of years he transformed a bare meadow into a secluded woodland retreat.

He died on April 9, 1940, in his eighty-fifth year.

J. RITCHIE.

Dr. W. E. Sumpner

THE death took place on May 8 of Dr. W. E. Sumpner, principal of the Birmingham Technical College during 1895–1930, in his seventy-sixth year.

He was appointed when the College (or School as it was originally called) was only four years old, and it was owing to his work and vision that it became such an important institution in this great industrial centre.

Sumpner was primarily a physicist and electrical engineer, and he was well known in scientific circles. In his early days he was connected with the City Guilds of London. In 1885 he took first-class honours in both mathematics and physics, and four years later he took the London D.Sc. He was then appointed fellow of University College, London, and fellow of the City and Guilds Institute. He was also fellow of the Physical Society, serving as vice-president for a time. For some of us in Birmingham perhaps he was best known and regarded as the genial president of a small scientific symposium known as the R^3, founded originally by the late Prof. Poynting, of the University of Birmingham, for those teaching science in the city. He married in 1901 Miss Lucy Weekes, who survives him with a son and a daughter.

J. H. REYNOLDS.

WE regret to announce the following deaths:

Prof. W. Blackadder, Jackson professor of engineering in the University of Aberdeen, on May 14, aged sixty-one.

Mr. E. R. Gunther, zoologist to the "Discovery" Committee, aged thirty-seven.

Prof. J. H. Muirhead, F.B.A., emeritus professor of philosophy in the University of Birmingham, on May 24, aged eighty-five.

NEWS AND VIEWS

Scientific Advisory Committee on the Nation's Food

THE Lord Privy Seal, as chairman of the Food Policy Committee of the War Cabinet, has appointed a committee "to consider and advise upon problems of national food requirements and of home food production with special regard to the shipping and foreign exchange likely to be available for imports of food and animal feeding-stuffs, and the labour and other resources likely to be available for home production".

The committee has been constituted as follows: *Chairman*, Sir William Bragg, president of the Royal Society and director of the Royal Institution; *Deputy Chairman*, Sir Alan Anderson; *Members*, Prof. A. W. Ashby, professor of agricultural economics, University College of Wales, Aberystwyth; Prof. E. P. Cathcart, F.R.S., regius professor of physiology, University of Glasgow; Dr. Henry Clay, formerly professor of social economics, University of Manchester; Prof. F. L. Engledow, F.R.S., professor of agriculture, University of Cambridge; Mr. W. Gavin, agricultural adviser to the Ministry of Agriculture and Fisheries; Sir Edward Mellanby, F.R.S., secretary of the Medical Research Council; Sir John Boyd Orr, F.R.S., director of the Rowett Research Institute, Aberdeen; Prof. J. A. Scott-Watson, professor of rural economy, University of Oxford; *Secretary*, Prof. D. M. S. Watson, F.R.S., Jodrell professor of zoology and comparative anatomy, University College, London, and member of the Agricultural Research Council.

FOR purposes of economy, the sections "Seventy Years Ago" and "Points from Letters" will be suspended after the termination of the present volume of NATURE, that is, June 29.

The Editors are particularly anxious to maintain the amount of space devoted to the more important sections of the journal. This applies especially to the correspondence columns; and, here, contributors are again asked to collaborate by reducing their communications to the absolute minimum. Letters should not exceed five hundred words in length, which corresponds to a column of text.

Monthly supplements of Short Reviews will also be suspended.

Chair of Physics at Sheffield: Dr. W. Sucksmith, F.R.S.

DR. W. SUCKSMITH, reader in magnetism in the University of Bristol, has been appointed to the chair of physics in the University of Sheffield. Dr. Sucksmith was educated at Hipperholme Grammar School and the University of Leeds where, after four years of service with the Army in the War of 1914–18, he graduated with first class honours in physics in 1921. He then joined the staff of the University of Bristol as assistant lecturer in physics, and was appointed lecturer in 1924 and reader in magnetism in 1939. He was awarded the D.Sc. degree of the University of Leeds in 1930, and has been elected a fellow of the Royal Society this year. Dr. Sucksmith is particularly distinguished for his work in experimental magnetism. Following a determination of the gyromagnetic ratio for ferromagnetic substances by the direct measurement of the mechanical rotation which accompanies magnetization, carried out by Chattock and Bates at Bristol, he confirmed their results with a null method. He later extended his measurements to deal with paramagnetic substances. This required experimental skill of a very high order, as the measurements were very much more difficult than those with ferromagnetic substances. In the course of this work it was necessary to measure the susceptibilities of paramagnetic oxides, and to this we owe the design of the Sucksmith ring balance, which has proved useful in many researches.

During the session 1933–34 Dr. Sucksmith held a Rockefeller fellowship at the Federal Technical College in Zurich, where he measured the gyromagnetic ratio for a series of nickel-copper alloys with low Curie points at temperatures above the latter, using the technique previously employed with paramagnetic oxides. Dr. Sucksmith has also made substantial contributions to our knowledge of the specific heats of ferromagnetic substances and of the magnetic properties of single crystals of nickel. More recently he has been engaged on experiments on the magnetic properties of ferromagnetic substances at high temperatures and on the saturation intensities of magnetization of a large number of ferromagnetic alloys, in which his ring balance has again been put to good use. Since 1937 he has been a member of the Permanent Magnet Sub-Committee of the Electrical Research Association.

Prof. S. R. Milner, F.R.S.

WITH the retirement in September of Prof. S. R. Milner, F.R.S., from the chair of physics, the University of Sheffield will lose the services of an eminent man of science and of an outstanding personality, who, during the past forty years, has been untiring in his efforts alike for the advancement of science, for his students, and for the University. A Yorkshireman by birth, Milner spent his early years in Retford, where he attended the King Edward VI

School. He then became a science student at University College, Bristol, and graduated from there in 1895. He spent two post-graduate years as an 1851 Royal Exhibition Scholar working under the late Prof. A. P. Chattock, for whom he has always retained warm feelings of admiration and affection, and a third year under Prof. Nernst at the Institut für physikalische Chemie in the University of Göttingen. During 1898–1900 he was a demonstrator in physics at the University of Manchester, and he recalls with pride that Sir Arthur Eddington was one of his students there. Milner left Manchester to take up a lectureship in physics at Firth College, later the University of Sheffield, under Prof. W. M. Hicks, who was successively principal of the College and the first vice-chancellor of the University, so that much of the work and organization of the department fell to Milner's lot. During the War of 1914–18 he served as assistant radiographer to the Third Northern General Hospital until 1917, when he was appointed acting professor of physics, on Prof. Hicks vacating the chair. Since 1921 he has been professor of physics, and in 1922 he was elected to the fellowship of the Royal Society.

In his research activities, Prof. Milner has shown himself to be a physicist in the widest sense, his researches having ranged over many fields, only some of which can be mentioned here. His earliest work was on the thermal conductivity of water (with Prof. Chattock). Later work was concerned with interference phenomena, with the non-reversible character of the formation of soap films, with the electric discharge in mercury vapour (in which connexion he discovered the principal series of mercury), and with the mechanism of the spark discharge, involving the analysis of lines in a rotating mirror and the characteristics of the oscillatory spark. By his pioneer work on the theory of strong electrolytes he anticipated the work of Debye. His more recent work has been concerned with the properties of the electromagnetic field in four dimensions, especially the theory of tubes of force and action in their four-dimensional aspects, and with the properties of Eddington's wave matrices. An experimentalist of no mean order, Prof. Milner is also a self-made theoretical physicist, so that his approach to theoretical work is always characterized by the physical rather than the purely mathematical outlook. Primarily due to this fact he has the rare ability of presenting intelligibly abstruse advances in modern physical theory to a general scientific audience. Many of his old students now occupy prominent positions in the scientific world, and all who know him or his work will join in wishing him many years of happiness and good health in his retirement.

Dr. W. L. H. Duckworth

THE election of Dr. Wynfrid Laurence Henry Duckworth to be Master of Jesus College, Cambridge, which was announced on May 28, is a well-deserved recognition of a devotion to the service of his College and University which is well-nigh lifelong. Dr. Duckworth, who is reader in anatomy, went to the University as a scholar of Jesus College, after receiving his earlier education in Birkenhead and at Dinan, Brittany. He graduated with first-class honours in both parts of the Natural Sciences Tripos in 1892–93, and during 1898–1920 was University lecturer in physical anthropology. His laboratory demonstrations and organization and arrangement of the museum specimens which came within his province contributed markedly to placing the Cambridge school in a unique position in anthropological studies; while so long ago as 1902, Dr. Duckworth's merit as an original thinker and teacher in anthropology were widely recognized on the publication of his two books "Morphology and Anthropology" and "Studies from the Anthropological Laboratory" (Cambridge). In the same year Dr. Duckworth was invited by a committee of the British Association to join the archæological expedition then excavating in Crete, for the purpose of investigating the racial characters of the ancient and modern inhabitants of the island. The report which he eventually produced is still of standard authority on this question. Dr. Duckworth, who was born on June 5, 1870, represented his University on the General Medical Council during 1923–26.

Colonial Development and Allied Co-operation

CERTAIN matters of no little moment in relation to scientific research and its application to problems of Colonial development were mentioned in the debate on the second reading of Mr. Malcolm MacDonald's Bill to which it was not possible to refer in NATURE of June 1 (see p. 853). Mr. MacDonald had stressed the facilities which the Bill would afford not only in erecting buildings for clinics, hospitals and schools, to which grants under the existing Colonial Development Act are confined, but also in assisting their maintenance after erection, as well as steadily increasing the opportunities for medical and veterinary research and of health measures of all kinds. The importance of the assistance in maintenance was more fully brought out by Sir Francis Fremantle, who stressed its importance in relation to education, which he urged should be directed towards the objects which appealed to the natives, namely, agriculture and health. His experience as a sanitary officer in Mesopotamia during the War of 1914–18 brought him into relation with various races whose intelligence—even of the most primitive of them—in malaria prevention after even a short course of instruction had astonished him. After referring to the results and needs of research on leprosy, he went on to point to the achievement on exiguous resources of small hospitals and clinics in Zuzuland. In research he urged that a great deal could be done in regard to the native population, especially in the matter of psychology.

An important aspect of the problems to which research in Africa, for example, will be directed was presented by Sir Jocelyn Lucas, who, in speaking of progress in the study of tropical diseases, stressed the importance in this, as well as in other respects, of co-operation with our French Allies. How far the War has fostered co-operation between French and

British medical and scientific men is indicated by "Medicus M.P. in France" (*Lancet*, June 1, p. 1031), who speaks of the constant consultations taking place between medical officers of divisions of the two forces and the meetings of French and British consultants, including distinguished civilians, at G.H.Q., at which views are exchanged, leading with numerous other facilities to a far greater degree of co-operation than during 1914–18. This readiness to co-operate and unity of purpose, it may be anticipated with no little confidence, will inspire the co-operation in Colonial administration in the future upon which the two Governments have agreed. Now that the resources of the Belgian Congo and Mandated Territory, upon which the Belgian Government has lavished expenditure, have been placed at the disposal of Belgium's allies, a valuable opportunity has arisen for laying the foundations of future research and co-ordinated action.

Blood-Group Tests and Paternity

In view of the application of blood-group tests in medico-legal problems involving disputed blood-relationship, it is interesting to note results of the test in a series of fifty cases which have been recorded by Dr. David Harley and Dr. G. Roche Lynch (*Lancet*, May 18, 1940). Most of the cases were affiliation cases; in these, as is well known, the blood test, while not establishing paternity, does eliminate false accusation by establishing non-paternity, the expected rate of establishment on the assumption that all men are falsely accused being approximately 32 per cent. In the present series, non-paternity was established in eight cases, or 16 per cent, a figure which suggests that about half the men were falsely accused, while half were in fact the fathers. The authors point out that while the percentage is not likely to be so high in the 5,000 affiliation cases heard in England and Wales in the course of a year, since in many of them paternity is not in dispute, but merely the amount of compensation, yet the fact that an appreciable number of men prefer to go to prison rather than pay suggests that the number of false accusations is by no means negligible. With improvement in the technique of identifying sub-groups, the utilization of these factors should add to the value of the test in such proceedings by raising the percentage of exclusions possible.

National Collections in London or in the Country?

A matter of very great importance to scientific workers in Great Britain and throughout the world is raised by Dr. Percy R. Lowe in an article discussing the threatened removal of the ornithological collections from the British Museum (Natural History) to Tring (*Museums J.*, 49; May 1940). It is there stated that "the Trustees of the Museum seriously contemplate transferring the national ornithological collections from South Kensington in London to Tring in Hertfordshire". That would indeed be a serious step, for no expert studies bird skins without using the books referring to the group upon which he is working. So that the ornithological library would have to follow. But many bird papers appear in journals not specifically devoted to ornithology; would the series of these journals also have to go, or would the expert be left in the lurch? That seems to be a problem not easily solved; Dr. Lowe discusses others. But indeed the proposal bristles with so many difficulties that it may be taken for granted that the Trustees will seek advice from scientific workers who are accustomed to study ornithological or other systematic collections, and will make no decision even for the future without the fullest inquiry and consultation.

The British Pharmacopœia: Emergency Monographs

The need for an addendum to the "British Pharmacopœia" which is now ready for official publication was dictated by war-time circumstances which deprived Great Britain of unfettered access to supplies of cod liver oil and olive oil and made it desirable to sanction the use of substitutes for both. The outstanding new monograph in the Addendum is on *oleum vitaminatum*, a vitaminized oil which is a solution of vitamins A and D containing 1,000 units of vitamin A activity and 100 units of antirachitic activity (vitamin D) in 1 gm. It is clear that the object of the Pharmacopœia Commission was to provide a standard for a substitute for cod liver oil which, in respect of its vitamin contents, should approximate to the natural product. The vehicle for the vitamins may be "a suitable vegetable oil" the choice of which is left to the manufacturer, with the suggestion that arachis oil would answer the purpose at least as well as any other. Provided the preparation responds to the characters and tests for purity laid down in the monograph, vitaminized oil may consist, alternatively, of a suitable fish-liver oil, or blend of fish-liver oils, thus allowing to commercial firms a generous latitude which is justifiable, and indeed advisable, in a time of emergency. Of the nine other new monographs in the Addendum, seven are related to the cod liver oil problem; they include standards for concentrated solutions of vitamins and for emulsions of cod liver oil itself and its substitute.

The only new monograph which is unrelated to cod liver oil is that on tetanus toxoid, which is officially described as "tetanus toxin, the sterile filtrate of a culture on a suitable medium of *Clustridium tetani*, or material derived therefrom, the specific toxicity of which has been completely removed by the action of chemical substances in such a manner that it retains efficient properties as an immunising antigen". Tetanus toxoid may occur as a simple solution of tetanus toxin or as alum-precipitated tetanus toxoid. The Addendum amends five monographs of the Pharmacopœia. The object of the alterations in some cases, namely, liniment of camphor and compound ointment of mercury, is to authorize the use of arachis oil, cottonseed oil or sesame oil in place of olive oil in making these preparations. In the case of capsicum ointment, the use is sanctioned of a simple ointment prepared with yellow soft paraffin in place of the present base which contains lard. A new formula is presented as a standard for tannic acid ointment. Five appendixes to the Addendum revise existing directions for as many processes; they relate to the determination of (1) ultra-violet absorption, (2) iodine value, (3) unsaponifiable matter in fixed oils and fats, (4) aldehydes or volatile oils, and (5) the assay of vitamin A.

Biological Films

THE Gaumont British Instructional Films Bureau has recently added some interesting biological films to its already extensive collection. "Climbing Plants" portrays clearly the many different devices for climbing adopted by plants in their struggle for existence, including 'scramblers', thorn, petiole and aerial root climbers, as well as types that climb by means of tendrils and stems. The photographs of circumnutation in the bean seedling are as excellent as the rest of the film. In "The Swan", the photographer has captured some entertaining 'shots' of the famous swannery at Abbotsbury, near Weymouth. Courtship and breeding are carefully presented, as well as pleasant recordings of cygnet development. "The Life-Story of a Fern" includes photographs of royal, hart's-tongue, male and bracken ferns, indicating methods of spore production and liberation. In this film some informative pictures of fertilization processes in the ferns are particularly noteworthy.

"The Emperor Moth" describes the complete life-cycle of the insect from the egg to the emergence from the pupal case. The value of this film, as of many other insect films, is that the activities and development of the insect over a period of weeks may be seen as a coherent picture within a few minutes. In "Marshland Birds" various island builders like the dabchick, great crested grebe, the coot, swan and moorhen are seen in various stages of their life-history, as also are shore-builders such as the snipe, wild duck, bittern, yellow wagtail, bearded tit, reed warbler and heron. Photographs of predators like the short-eared owl and the harrier are included in order to introduce an ecological concept. In this film the photographer has secured many pictures which must be ranked well outside the usual. The appearance of these five films bears witness to the continued technical progress that is being made in the production of biological films.

Observation of Chimpanzees

AN experimental laboratory for the observation of behavioural development and adjustment, growth and maturation of chimpanzees has recently been established at the Yale Laboratories of Primate Biology, Orange Park, Florida. Infants are to be separated from their mothers at birth and reared under controlled conditions as subjects of a special research by Dr. Henry W. Nissen, assistant director. Up to March 1940, Prof. R. M. Yerkes records (*Science*, 91; April 5, 1940), 34 infants have been born in the colony, which contains 27 individuals of known birth-date and recorded life-history out of a total population of 47, ranging in age from four days to twenty-seven years. Several of these chimpanzees have resided in the colony for 8–14 years. Though the normal life of this great ape in captivity has not been determined, it is indicated that the reproductive life may exceed thirty years, while probably in favourable conditions the individual may live for fifty years. The average interval between generations in the breeding colony is almost exactly nine years.

With regard to the special problems of behaviour, it may be noted that of two primiparous mothers, neither accepted nor cared for their infants at birth. Each behaved as if surprised and bewildered, while lacking suitable, ready-to-hand patterns of behaviour for the novel emergency. Nor did either consume the afterbirth. By contrast, multiparous mothers usually eat at least part of the afterbirth and almost invariably treat the new-born infant as a familiar object, handling it skilfully and ensuring its welfare. The structurally determined maternal behaviour of the primiparous chimpanzee is importantly supplemented by acquisitions resulting from individual reproductive experience and also by social tradition.

Control of Weeds and Grassland Experimentation

THE Imperial Bureau of Pastures and Forage Crops, Aberystwyth, has recently published three new bulletins. No. 27, "The Control of Weeds" (7*s.* 6*d.*), is a symposium dealing with the various aspects of the problem as it occurs in different parts of the world, particularly in the British Commonwealth and the United States. Increasing attention is being paid to this question; extensive research work on cultural, chemical and biological means of control is in progress, and important results are already available. The practices characteristic of each country make interesting comparison. The outlook regarding chemical measures of control, for example, is very different in the United States and Germany, stress being laid on the value of cultural methods in the latter case. In Australia and New Zealand biological means have been used, with spectacular success in the eradication of prickly pear in Australia. Poisonous weeds are the subject of an article from South Africa, while Canada's contribution is chiefly ecological.

Bulletin No. 28 (2*s.* 6*d.*) describes the "Technique of Grassland Experimentation in Scandinavia and Finland". This includes both the technique for the quantitative measurement of grass production and that of stock-grazing trials. The methods of grassland analysis are chiefly contributed from Denmark and Sweden, while the grazing experiments described were carried out in Norway and Finland. Bulletin No. 29 (5*s.*) is entitled "Grassland Investigations in Australia". This publication may be regarded as a continuation of Bulletin No. 14 issued in 1934, which dealt with a similar subject. The enormous variation in climate naturally raises very diverse problems in the different parts of the country, but in general the pasture investigations cover two main features, natural pasture maintenance and regeneration, and the treatment of sown pastures, together with the problems of the winter and summer rainfall zones.

Fifteen special articles are included in this bulletin, as well as brief abstracts of recent publications on grassland in Australia.

Power Development in Turkey

ENERGETIC steps are now being taken by the Government to open up the market in the south-east corner of Europe to British industry. According to the *Electrical Times* of May 2, one of the first results of this active trade policy was shown by the recent announcement of the signing of a contract between the Turkish Government institution known as the Eti-Bank and the Metropolitan-Vickers Electrical Co., Ltd., which has a value of approximately one and a half million pounds. A few details of the contract are available. It covers the electrification of a large and important area, including the construction of a power station at Catalagzi on the Anatolian coast of the Black Sea. One of the main objects of the scheme is the provision of electric power for the modernization and expansion of the Turkish coal industry, and the site of the power station has been chosen for its proximity to the Zonguldak coal basin, from which the station fuel will be derived. The present contract includes the building and equipment of a 60,000 kw. steam power station, and the provision of switchgear, overhead lines and three substations for a transmission system about 16 km. in length. Provision is to be made for the extension of the scheme at some future date.

The initial generating plant will consist of three 20,000 kw. turbo-alternator sets, to operate at 3,000 r.p.m., with Metrovick central flow condensers and four-stage feed-heating, incorporating low-pressure evaporators for make-up supply. Sea-water will be used for cooling and will be supplied from a separate pump-house to be constructed on the shore. The main alternators will generate at 11,000 volts; and each set will include a 1,500 kw. house-service alternator. A 375 kw. Diesel engine set will also be provided for stand-by service to the station auxiliaries. Transmission to the substation will be at 66,000 volts, the station output being stepped up to this voltage in an outdoor transformer and switching station adjoining the power station and controlled from an indoor controlled board. The main transformers will be 25,000 kva., 11/16 kv., 3-phase units. The equipments of the substations will include nine 6,400 kva., 66/15 kv. outdoor transformers and 15 kv. indoor switchgear.

Alluvial Gold Dredging in the Gold Coast Colony

AN interesting account is given in the *G.E.C. Journal* of February of the electrical equipment for the Bremang Gold Dredging Co., Ltd. This company dredges for alluvial gold on the Ankobra River, one of the larger rivers of the Gold Coast Colony, which flows roughly north and south and pours itself into the Gulf of Guinea. Many of the shallows of the river are sufficiently rich in alluvial gold deposits to warrant commercial development, and the Bremang Gold Dredging Co., Ltd., has installed equipment at two of these points for dredging mud and gravel from the river bed from which the gold is recovered. The dredges are electrically operated and are supplied from individual substations fed by a 55 kv. overhead transmission line from the power station of Ankobra Junction, a distance of about twenty miles.

The power station and the various camps from which the dredging operations are conducted are situated some 6° north of the equator in what was originally bush country with a humid tropical climate, but very great improvements in living conditions have been made in recent years. The bungalows provided for the accommodation of the European staff are of the most up-to-date type, with modern sanitary arrangements, electric light, fans, and running water supplied from specially constructed tanks. As regards diet, most of the vegetables are canned, but fresh potatoes are obtainable from Madeira, and green vegetables, such as lettuce and cabbage, can be grown locally provided the soil is adequately watered and sheltered from the sun. Cheese and butter are also available, and can now be kept in good condition almost indefinitely as a result of the installation of domestic refrigerators in the bungalows. Wireless programmes are provided by a local company at Prestea, and a relay station has been instituted in each camp with loud speakers in the individual bungalows. The native labour employed is recruited from local villages.

New Type of Rubber Paving Block

IN *Roads and Road Construction* of May 1 it is stated that Marylebone Borough Highways Committee reports that Universal Rubber Paviours, Ltd., of Manchester, have offered to provide and lay, free of cost to the Council, approximately 300 square yards of a new type of rubber paving block. The Council has already approved of the renewal of the concrete foundation and wood paving in Duke Street (Wigmore Street to Edward's Mews) which is considered to be a suitable site for the rubber paving. Other alternatives have been considered, but as the paving is to be subjected to skidding and other tests by the Ministry of Transport, it is necessary for the whole width of the carriageway to be paved with rubber and the section of Duke Street in question is of the desired width and length for the tests. The acting borough engineer reports that the new type of block appears to be an improvement on those laid by the same Company in Allsop Place, by Clarence Gate, some six years ago. By accepting the offer, the Council will save approximately £400 on the provision of wood blocks for the section of the carriageway in question.

National Radium Trust and Radium Commission

THE tenth annual reports of the National Radium Trust and Radium Commission (1938–1939) follow the general form of previous reports, but constitute, owing to special difficulties in planning for future developments, a more tenuous publication than usual. One of the most important events external to the chief work of the Commission has been the passing of the Cancer Act on March 29, 1939; this naturally receives a welcome from the Commission, and has been followed by an enlargement of the personnel of that body. As is generally known, the effect of the Act is to throw upon the major local authorities, county and county borough councils, the duty of securing proper facilities for cancer treatment on behalf of people in their areas; this will of necessity call for close collaboration with members of the Radium Commission whose knowledge and experience of radiological methods as practised in all the important centres in the country should secure a high level of efficiency in treatment and economy in practical methods.

Mortality in New York Hospitals

DURING 1938, the mortality-rate in the New York City hospitals for contagious diseases fell to 1·8 per cent, the lowest to date. This figure compares favourably with a 4–6 per cent mortality in general hospitals. There were 2,109 cases of whooping-cough admitted to hospitals in 1938, or more than for any year in the last two decades. Of all the cases of diphtheria notified to the Health Department in 1938, 43·7 per cent were admitted to hospital, while 31 per cent of the scarlet fever cases, 8 per cent of the measles cases and 16·1 per cent of the whooping-cough cases were sent to hospital.

Antiquities from the Eumorfopoulos Collections

ONE of the most interesting and important items in the sale of part of the Eumorfopoulos collections which took place at Messrs. Sotheby's rooms during May 28–31 was a third century B.C. toilet box. This was purchased by the National Arts Collection Fund for presentation to the British Museum (Bloomsbury). It is described as circular, with a diameter of 8¼ inches and a height of 5½ inches. It is decorated in greenish-red lacquer on a thin layer of fabric. The straight sides and domed top are ornamented with scrolls, birds and stylized animals, while on the sides of the cover are represented a horseman, a tiger and a charging bull on a chocolate brown ground enriched with silver inlay. With the box was a bronze mirror of the Warring States period (*c.* 481–221 B.C.) which had been found inside it. Among other antiquities of special interest was an example of the remarkable and rare bronze-covered wine vessels of the little-known Shang Dynasty (? 1766–? 1122 B.C.), this specimen having a silvery-green and red-brown patina, a Kmer female torso in grey limestone of the eleventh century of our era, a period of perhaps the greatest efflorescence of the Kmer art of south-eastern Asia, and the magnificent gold furnishings of a fifteenth century Ming emperor's tomb.

Recent Earthquakes

DURING May 18–19, fifty people were killed and many injured at Mexicali near the border of the United States, where houses and Government buildings were damaged. Fifteen earthquakes were felt. In Africa strong shocks were felt on the night of May 19 on the Zululand coast, in Natal, in the Transvaal and in the Limpopo area. The epicentre may have been off the Zululand coast. Local tremors were felt in the Rand. About 23.55 G.M.T. on May 18 local tremors were felt at Deganwy, North Wales, by Mr. Willoughby Gardner, who reported the matter to *The Times*. These may have been due to movement along the Conway fault system.

Over the same week-end strong shocks were recorded on Mr. J. J. Shaw's seismographs at West Bromwich, and Father Rowland states that the seismograph at Stonyhurst College Observatory recorded a strong shock lasting about three hours, commencing on May 19 about 4.40 G.M.T. At Kew the seismographs commenced recording on May 19 at 4h. 48m. 53s. G.M.T. and finished at 7h. 45m., with a maximum ground amplitude at Kew of 0·029 mm. A second shock was registered at Kew at 15h. 29m. approximately on the same day, though this was only small.

Announcements

IT is announced that the British Association has reluctantly decided to cancel the Conference on Science in National and International Aspects which was to have been held at Reading during July 25–27.

MR. T. L. ASQUITH, chemist, Royal Ordnance Factory, has been appointed an additional member of the Civil Division of the Order of the British Empire, for services in connexion with an explosion at the Royal Ordnance Factory on April 2.

THE following officers for 1940–41 of the Royal Aeronautical Society have recently been elected: *President*, Dr. A. H. R. Fedden; *Vice-Presidents*, Mr. Griffith Brewer and Air Vice-Marshal R. M. Hill; *Honorary Treasurer*, Major D. H. Kennedy; *Honorary Librarian*, Mr. J. E. Hodgson; *Secretary and Editor*, Captain J. Laurence Pritchard.

MR. DONALD C. BRADFORD has been appointed seismologist at the University of Pittsburgh. The seismological station is in the basement of the "Cathedral of Learning", a skyscraper close to the main traffic arteries of the city. It has been found that the two Wenner horizontal seismometers and the Benioff vertical seismograph function quite satisfactorily, contrary to expectations before 1931 when the site was tested and recording began.

THE sixth University in the Argentine Republic has recently been founded at Mendoza.

MORE than 9,000 natives died from malaria in the Transvaal during the year ended March 31, 1939. According to the Department of Public Health the heavy rains at the end of 1938 and the beginning of 1939 made conditions favourable for malarial mosquitoes. The chief difference between this epidemic and that of 1937 was not one of severity but of extent, the 1939 epidemic reaching over a greater area and going so far south as Pretoria.

LETTERS TO THE EDITORS.

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 901.

Excited States of Stable Nuclei

WE have recently carried out some experiments on the scattering of protons by light elements, using the proton beam provided by the Liverpool cyclotron and detecting the scattered particles by the photographic method.

A proton beam of about 10^{-8} amperes, with a divergence of one degree, is defined by a system of stops, and emerges from an attachment to the vacuum tank of the cyclotron into the 'camera' through a mica window covering a hole $\frac{1}{8}$ in. in diameter. In the camera this narrow proton beam passes down the axis of a tube, which is interrupted for a length of 3 mm. to allow the scattered particles to emerge. A flat photographic plate is placed so that its surface is parallel to the axis of the beam and at a distance of 1 cm. from it. The protons scattered by the gas with which the camera is filled emerge through the interruption and enter the plate at a small glancing angle. This arrangement has the advantage that a single plate can contain the information for determining the probability of scattering from about 15° to 150°, providing for each angle regions containing a suitable number of tracks for counting purposes. At the same time, the energy of the scattered particle can be determined from the length of its track in the photographic emulsion.

Once the difficulties of defining the beam in the stray field of the magnet had been overcome, we found that suitable exposures could be obtained for some six to eight different scattering gases per day.

We have taken plates of the scattering from eleven elements which could be obtained either as elementary gases or in the form of suitable gaseous compounds. The energy of the incident particles at the point of scattering was about 4 million volts. The plates for hydrogen, deuterium and helium are satisfactory, and work is proceeding on these; but we wish to direct attention here to the inelastic scattering which accompanies the elastic scattering from the heavier elements, and gives information about the excited states of the stable nuclei in a particularly direct way.

The distributions in energy of the protons scattered through 90° from the gases oxygen and neon are shown in Fig. 1. In oxygen a single peak appears, corresponding in energy to protons elastically scattered through 90°. With neon, in addition to the elastically scattered group, there is a peak at lower energy which we attribute to inelastic scattering from ^{20}Ne. This view is supported by the fact, deduced from the analysis of the neutron spectrum of fluorine under deuteron bombardment, that ^{20}Ne has an excited state of 1·4 Mev., for the difference in energy of the two groups of scattered particles is just of this amount.

We have examined the variation of the probability of scattering with angle for elastic and inelastic scattering in neon, and the results are shown in Fig. 2. It will be seen that in the range from 40° to 80° the elastic scattering follows very closely that expected from pure Coulomb scattering. In contrast with this, the inelastically scattered particles are distributed spherically symmetrically about the centre of mass of the system, to within the present accuracy of the measurements. This suggests that the inelastically scattered protons have been 'evaporated'

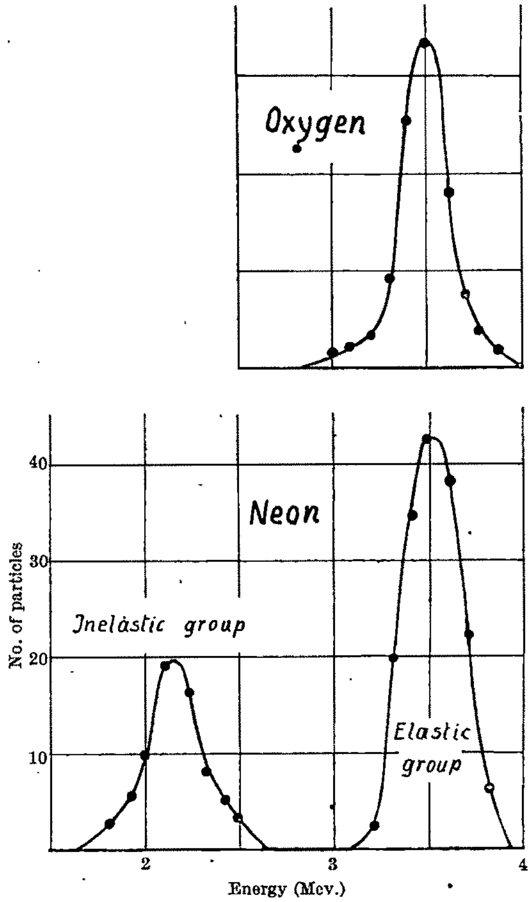


Fig. 1.

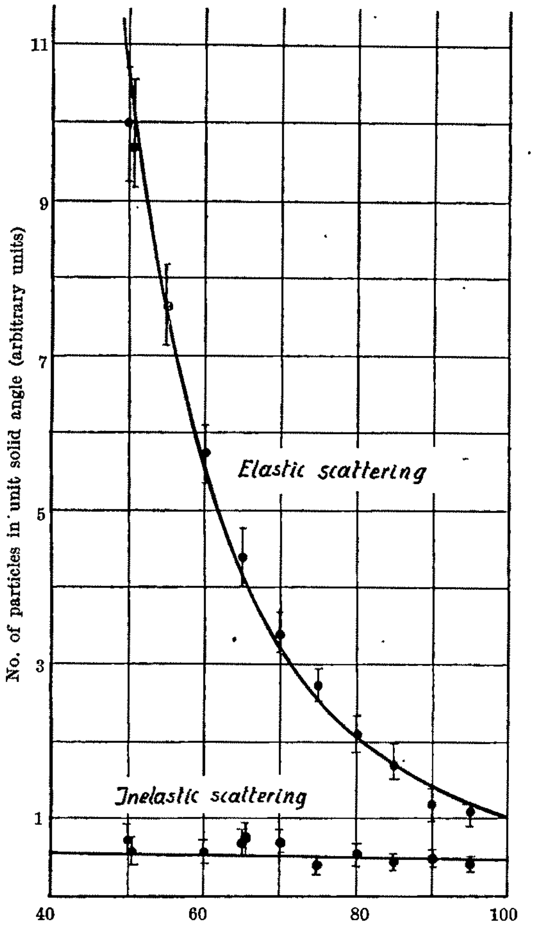

Fig. 2.

from the compound nucleus formed in a close collision of an incident proton and a ^{20}Ne nucleus.

The absence of inelastically scattered protons in oxygen in the conditions of our experiments is evidently due to the fact that there is no excited state of oxygen below 4 Mev. The variation of scattering with angle shows, however, strong anomalies from Rutherford scattering at angles greater than about 45°, the number of scattered particles per unit solid angle varying only slowly with angle. This point will be investigated further.

With the elements of atomic number greater than that of neon which we have examined, such as chlorine and argon, the ratio of the number of inelastically to elastically scattered particles is very much smaller than in the case of neon, corresponding to the decreasing probability of the protons entering the nucleus with increasing nuclear charge. It is therefore evident that it will be desirable to continue the experiments with protons of higher energy in order that the higher excited states of the light elements may become accessible to investigation, and to obtain results for elements of higher atomic number. It is clear from our experience, however, that the method is very powerful, the plates being obtained with an exposure of a few minutes and the analysis of the energy distribution of the scattered protons being complete within a few hours. Also the use of what are essentially gas targets gives the advantage of purity control and absence of effects associated with energy loss in the target. We may expect these advantages in experiments of a similar character with high-energy deuterons, where the scattered primary particles may be accompanied by disintegration products.

In general, we may conclude that, using the photographic method of detection, it becomes possible to take advantage of the high-energy particles provided by the cyclotron to make experiments of the kind which have hitherto only been undertaken with direct current generators at relatively low energies.

Photographic Plates as Detectors of Mesotron Showers

During the last two years we have been using photographic plates (Ilford R_2 and New Halftone) for the study of cosmic rays at different altitudes. Both treated and untreated plates have been used for the purpose. In the present communication is reported the results obtained by keeping for five months untreated New Halftone plates in cardboard containers, vertically on their long sides, at Darjeeling (Mayapuri Research Station, elevation 2,130 m.) and at Sandakphu (Dak Bungalow, elevation 3,660 m.).

In the plate kept at Sandakphu, on an area of 0·5 cm.^{2} were observed 40 long single tracks, 15 double, 8 three-star, 12 four-star, 3 five-star, and one each of six- and seven-star tracks. Blau and Wambacher[1], whose technique we have followed, kept similar untreated plates at Hafelekar (2,300 m.) for five months. They obtained a large number of long single tracks and also a number of stars, but apparently no double tracks. On the assumption that the tracks are due to protons, they have calculated their kinetic energies. For this purpose they have used a calibration curve expressing the kinetic energies of the ionizing particles as a function of the mean grain distance along their tracks. The maximum energy for a star was found to be 103 × 10^6 ev., with a mean energy of 16 × 10^6 ev. per track.

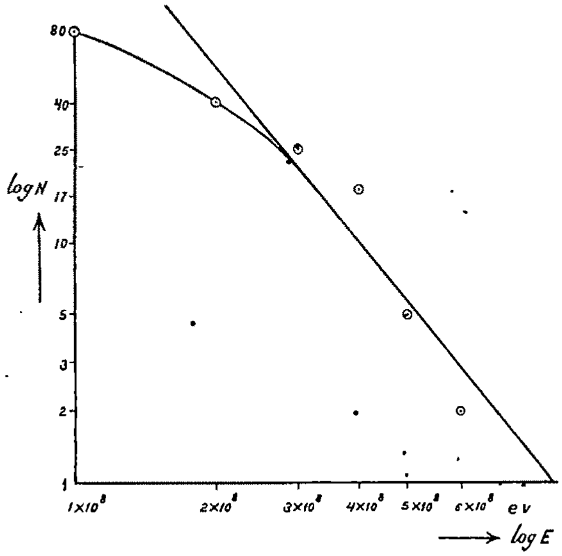
In the absence of such a calibration curve, we have calculated the energies of the particles in our plate from their measured track lengths on the emulsion. We also made the tentative assumption that the tracks are due to protons, and their kinetic energies were found to be of the order of 10^6 ev. This represents a minimum estimate of their kinetic energies. In view of the recent discussions on the nature of the small-angle penetrating showers, attributed to mesotrons by Bothe and Schmeiser[2], our attention was first directed to the pair tracks found in the plate kept at Sandakphu. Of the fifteen pair tracks, thirteen had angles between 6° and 21°, and one had an angle of 24° and the other 35°. Their kinetic energies varied from 2 to 4 Mev. It appeared plausible to make the assumption that these tracks were due to mesotron pairs, and to apply to them the formula given by Wentzel[3], limiting the angular spread θ of such showers, where $\theta \lesssim \frac{\bar{\lambda}}{a} \lesssim \frac{\hbar c}{\varepsilon a}$, in our case $\varepsilon = z(x + \bar{\varepsilon})$ where x is mass energy of a mesotron $\sim 10^8$ ev., $\bar{\varepsilon}$ is average kinetic energy of mesotrons in these pairs, $\sim 2 \cdot 9 \times 10^6$ ev.; and $\bar{\theta}$ is mean angle of scattering, $\sim 8°$.

In view of the relative order of magnitudes of x and $\bar{\varepsilon}$, not much error is introduced in calculating $\bar{\varepsilon}$ on the assumption that the tracks are due to protons and not mesotrons. For low velocities, the densities of ionization along the tracks of protons and mesotrons, for equal range in air, are of the order of 1·3 to 1.

We have calculated the value of a, the linear dimension of the scattering centres inside a nucleus on which mesotron packets, created by the impact of high-energy cosmic-ray particles on nuclear protons or neutrons, are scattered. The value of a is found to be $6 \cdot 7 \times 10^{-13}$ cm., which is comparable with the electron radius $2 \cdot 8 \times 10^{-13}$ cm.; it is of the right order of magnitude.

Next we proceed to the consideration of the origin of the star-like tracks. All of them contain tracks of the same nature, but in a few can be seen in addition one or two tracks due to heavier charged particles. For calculation we have assumed them all to be due to mesotrons. It is not clear whether the reasoning used by Wentzel can be applied to a multiple track shower. We have therefore made use of the hypothesis of multiple particle emission introduced by Heisenberg[4], according to which during the impact of a high-energy cosmic-ray particle with a nuclear proton or neutron, a part of the virtual mesotron field of the latter is radiated away as a mesotron wave packet. The latter is confined initially to a very small volume, but due to interference between parts of the wave packet, a number of secondary mesotrons are produced. If ε is the energy made available during the impact, then on an average $\bar{n}$ mesotrons will be produced where $\bar{n} = \varepsilon/n \log \varepsilon/x$, and the mean energy of a mesotron is $x \log \varepsilon/x$, which is nearly a constant. To a first approximation our results appear to be in agreement with the above. Each star on our plate represents an energy transformation, $\varepsilon = n(x + \varepsilon^*)$, where $n = 1, 2, \ldots 7$, and $\varepsilon^* \sim 10^6$ ev.

In the accompanying graph, we have plotted the curve $N = A\varepsilon^{\gamma}$, where N represents the number of stars with energies greater than ε. The value of γ, the tangent to the straight portion of the curve, comes out to be 2·5, which is of the accepted order, as others have found it to vary from 1·8 to 2·5.



It therefore appears probable that the tracks found in the Ilford Halftone plates are mostly due to secondary mesotrons. We have computed the total energies of these mesotron tracks per unit area of the plates kept at Sandakphu and at Darjeeling; their ratio is found to be 2·3, which is near the value of 2·0 obtained for the ratio of the ionization at these two altitudes from the curve given in Swann and Danforth's paper[5].

The soft component of the cosmic radiation may be considered to be responsible for their origin. The pair-tracks give no indication of being due to any fast primary ionizing particles, and are probably of photonic origin. Their kinetic energies are of the order of $10^6 - 10^7$ ev., and they are of the same nature as the slow mesotrons postulated as accompanying fast mesotrons by Maier Leibnitz[6]. That a portion of these slow mesotrons can be of photonic origin is admitted by the latter. Further evidence about the existence of these slow mesotrons will be found in Bothe's paper. A detailed account will be published in the *Transactions of the Bose Institute*.

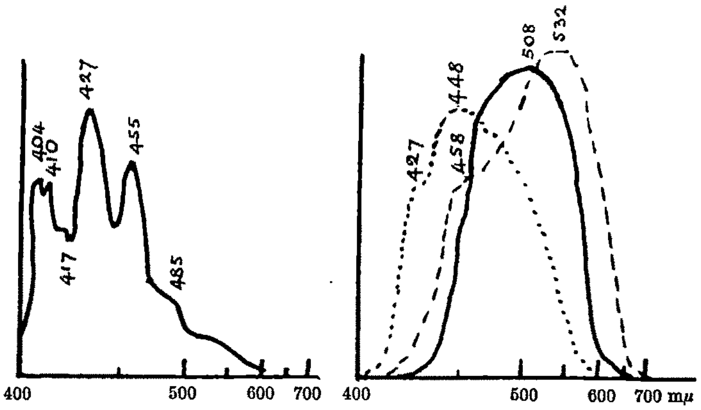
Some Physico-Chemical Properties of 3 : 4,Benzpyrene

IN contrast with the characteristic fluorescence spectrum (Curve 1) which 3 : 4,benzpyrene always emits when it is dissolved in solvents, we have observed three different types of fluorescent spectra (Curves 2, 3, 4) when the hydrocarbon was excited in the solid state. The needles of a commercial benzpyrene (La Roche) emit a green fluorescent light and we call it therefore the 'green' form. Curve 2 exhibits a broad rather symmetrical band with its flat maximum between 500 and 510 mμ. On pouring an acetone solution of the green form of benzpyrene into cold water there results the well-known colloidal suspension of benzpyrene which emits a yellowish fluorescence. The spectrogram of this 'yellow' form has its maximum between 530 mμ and 540 mμ, and a typical inflection at the short wave-length side of the band (Curve 3). On heating the green form in an evacuated tube, a white sublimate is formed on the tube walls which fluoresces brightly blue. The spectrogram of this 'blue' form shows a maximum between 445 mμ and 450 mμ, and an inflection on the short-wave-length side which appears as a contrast band at about 425 mμ (Curve 4). The sublimed crystals are small plates with typically curved edges. We believe that they are identical with the modification of benzpyrene which Iball[2] obtained from a solution in amyl acetate. According to his X-ray analysis, they are orthorhombic, while the needles (our green form) belong to the monoclinic system. Iball did not examine the fluorescence of either form.



Curve 1.

Curve 2, full line; curve 3, broken line; curve 4, dotted line.

PHOTOMETRIC CURVES OF THE SPECTROGRAMS ON PANCHROMATIC PLATES OF THE FLUORESCENCE OF 3 : 4,BENZPYRENE (1) DISSOLVED IN ACETONE AND (2–4) IN VARIOUS SOLID FORMS. THE GRAPHS WERE RECORDED WITH GOLDBERG'S[1] (1910) DENSOGRAPH, WHICH SERVED AS A PRIMITIVE MICROPHOTOMETER.

The three modifications of benzpyrene undergo several spontaneous transformations. (1) The green form is transformed into the blue form at high temperatures. The lowest temperature at which we observed the disintegration of the clear original needles was 67°. (2) The blue form is changed into the green form at low and moderate temperatures. This change of the plates into the needles can be easily seen under the microscope if one moistens the crystals of the blue form with a drop of any solvent. We observed it still at 65°. (3) The yellow form goes over into the blue form on keeping the colloidal suspension for a few hours at 100°. It is also quickly transformed into the green form at ordinary temperature by moistening the dry residue from the evaporated colloidal suspension with a drop of amyl acetate.

It follows from (1) and (2) that the green and blue forms are enantiomorphous modifications of benzpyrene with a triple point at about 66°. According to the thermodynamics of heterogeneous systems, the work done during the spontaneous transformation of one mole is :

$$W = RT \ln \frac{p_{\text{bl}}}{p_{\text{gr}}} = RT \ln \frac{s_{\text{bl}}}{s_{\text{gr}}},$$

where p_{bl}, p_{gr}, s_{bl}, s_{gr} are the vapour pressures and solubilities of the blue form and the green form, respectively. Because below 66° the green form is more stable than the blue form, the solubility of the blue form is greater than that of the green form, and *vice versa* above 66°. This is true for any solvent, and in particular we know now which form has at a given temperature the higher solubility in water, though the solubility of neither form has been directly determined.

From the transformation (3) it follows that the yellow form has the highest solubility of the three forms at all temperatures. This is consistent with the assumption that the yellow form is a microcrystalline form of the green form. The order of the solubilities below 66° is $s_y > s_{\text{bl}} > s_{\text{gr}}$, and above 66° $s_y > s_{\text{gr}} > s_{\text{bl}}$. In the same order the modifications may undergo spontaneous transformations with release of free energy.

We have also examined mixtures of colloidal suspensions of benzpyrene with cholesterol. With large amounts of benzpyrene the spectrum was the same as that of the yellow form (Curve 3). With decreasing amounts the composition of the mixed spectrum shifted from Curve 3 to Curve 4 and then to 1. The fluorescence colour of these mixtures was liable to a typical change which happened very slowly at room temperature but more quickly at elevated temperatures. The spectrum approaches more and more that of the blue form.

Because we know that the blue form represents below 66° an intermediate stage between the quite unstable yellow and the stable green form of benzpyrene, it follows from the experiments that this intermediate blue stage can be stabilized by the presence of cholesterol. The stabilization cannot be but temporary owing to the tendency of the blue form towards spontaneous transformation into the green form with release of free energy.

It is possible that these facts account for the biological activity of benzpyrene. It may be that, as with cholesterol, the lipoids of the cell coming into contact with benzpyrene stabilize its unstable form temporarily. The spontaneous transformation into the stable form may release energy for biological action. Experiments from this point of view are in progress with various carcinogenic compounds.

The research was supported by a grant from the British Empire Cancer Campaign for which we are very grateful. We are indebted to Prof. C. K. Ingold and Dr. C. F. Goodeve for the loan of a spectrograph.

Latent Energy and Dissociation in Flame Gases

THE gases remaining after flame has spread through an inflammable mixture are not just hot normal gases. The view has been put forward[1] that they contain a considerable latent energy in stable form. This probably resides in a proportion of the newly formed triatomic molecules as excess intra-molecular energy which cannot be handed over to the translational degrees of freedom. In virtue of the excess intra-molecular energy, it would appear that there is a much larger dissociation in flame gases than in normal gases of the same composition under similar conditions of temperature and pressure.

Two series of experiments which we have recently completed seem to us to lend strong support to these views. They relate to temperature determinations in flame gases carried out by means of change of resistance measurements of thin platinum-rhodium wires (0·0005 in. diameter) and of quartz-covered platinum wires (overall diameter 0·0005 in.) immersed in the gases.

The first series of experiments was made during the pre-pressure period in large closed-vessel explosions of mixtures of carbon monoxide and air of various mixture strengths. During this period, as is well known, a considerable volume of inflammation takes place at sensibly constant pressure. The results of these experiments are summarized in the curves in Fig. 1. It will be noticed that for very over-rich mixtures (50 per cent carbon monoxide and more) the two wires show the same temperatures, but for weaker mixtures the plain wire temperatures are much greater than the quartz-coated wire temperatures—nearly 400° C. greater for the combining proportions mixture. The shape of the quartz-covered wire temperature curve suggests abnormally large dissociation of the carbon dioxide in the products of combustion, which tends to be more and more suppressed as the concentration of carbon monoxide is increased. The high temperatures of the plain wires appear to result from the combination on their surface of the abnormally dissociated carbon dioxide.

In the second series, the temperature distribution was determined by means of the two types of wire along the radius of a sphere of 18 in. diameter *after* the completion of the explosion of a centrally ignited inflammable mixture consisting of 10 per cent carbon monoxide plus 7 per cent hydrogen and air. The curves in Fig. 2 summarize these measurements. It will be seen that the temperature gradient from the centre outwards as shown by the quartz-covered wire is not very large, but the point to which we wish to direct special attention is that whereas the difference between the plain and the quartz-covered wire temperatures is relatively small towards the end of the radius, it is very large (amounting to some 300° C.) near the centre. In order to explain these results it appears to be necessary to assume that the abnormal dissociation is greatest in the gases first ignited and decreases in those ignited later. Experimental results previously reported suggest that the latent energy in the flame gases left behind the flame front decreases with distance of flame travel from the igniting sources[1,2], and, assuming that the amount of abnormal dissociation varies with the latent energy, the results now reported would appear to be in line.

Latent Energy and Dissociation in Explosions

The suggestion has been put forward by Prof. David and Mr. Pugh[1] from the results of flame temperature experiments that the large latent energies found in flame gases, due probably to excess intramolecular energy in the triatomic molecules formed during combustion, facilitate the dissociation of the products, with the result that excessive dissociation is observed. The results of a number of closed-vessel explosion experiments confirm this view, and also indicate that the degree of such dissociation is, as would be expected, dependent on the amount of latent energy associated with the products of combustion.

It has been shown by David, Brown and El Din[2], and David and Leah[3] that the latent energy in explosions is dependent on the size of the explosion vessel used and also upon the initial density of the inflammable mixture. Series of explosions of carbon monoxide and air mixtures recently carried out in redesigned apparatus at initial pressures of ½, 1 and 3 atmospheres in two spherical vessels of 6 in. and 17·45 in. internal diameter may be used to determine the equilibrium constant for the reaction

$$2\,CO + O_2 \rightleftarrows 2CO_2$$

by the method of Fenning and Tizard[4]. The average latent energy varies with the initial conditions and an interesting correlation can be made.

The results are shown in the table below. The initial pressures are given in the first column, the maximum temperature attained in the second column and $\log_{10} \dfrac{Kp\text{ obs.}}{Kp\text{ theor.}}$, *Kp* obs. being the calculated equilibrium constant and *Kp* theor. the theoretical quantum value, in the third column. In the last column the average latent energy found is given. Comparison of the figures given in the last two columns shows the

Pi Atmos.	*Tm*° K.	$\log_{10} \frac{Kp \text{ obs.}}{Kp \text{ theor.}}$	L. E. % heat of combustion
	Large Explosion Vessel		
½	2590	0·47	5·0
1	2650	0·40	3·5
3	2750	0·32	2·5
	Small Explosion Vessel		
½	2510	0·81	7·0
1	2585	0·67	6·0
3	2645	0·73	5·5

remarkable proportionality between $\log_{10} \frac{Kp \text{ obs.}}{Kp \text{ theor.}}$ and the latent energy, indicating the dependence of abnormal dissociation upon latent energy.

Diffusion in Palladium

THERE has been considerable discussion[1,2,3] as to why the rate of diffusion of hydrogen through metals, instead of reaching a limiting constant value, continues to obey a $\sqrt{p}$-law even when the pressure p is several hundred atmospheres. Recently the view was advanced[3] that although the pressure outside the metal may be high, owing to a slow rate of transport through the boundary

adsorbed layer → metal

as compared with a rapid diffusion within the metal, there is always only a small concentration just inside the metal, which is built up according to the $\sqrt{p}$-law. If, however, it can be built up sufficiently, the concentration just inside the metal will approach the saturation value, and the $\sqrt{p}$-law can then no longer hold. This condition has previously never been realized.

Two circumstances would contribute to the breakdown of the $\sqrt{p}$-law : (*a*) a very high rate of supply of atoms to the metal surface ; (*b*) a high rate of transport across the surface.

To achieve (*a*) caustic soda solutions were electrolysed (at considerable current density) with a palladium tube as cathode. (*b*) requires a freshly oxidized and reduced palladium surface[4]. Of several tubes, only one gave the desired surface activity, which decreased successively between experiments, and gave the following results : (i) in its most active state the palladium showed a permeation rate for hydrogen *independent of current density* ; (ii) in its next most active state the curve between permeation-rate and $\sqrt{I}$ (I is current density) was parabolic (convex to the $\sqrt{I}$ axis) ; (iii) with successive stages of deactivation the curve approached a linear form.

These and other results on diffusion in metals will shortly be discussed more fully. The present results afford very satisfactory evidence of changes in the relative velocities of phase boundary reactions and of diffusion with time, and of the theory of diffusion discussed earlier[3].

Solar and Terrestrial Relationships of March 23-29, 1940

IT is of interest to compare Father Rowland's account[1] of the great magnetic storms in the last week of March with the record of disturbances in the solar chromosphere during the same period.

The first bright chromospheric eruption of great intensity was observed with the Greenwich spectrohelioscope in $H\alpha$ light on March 23 at 11h. 30m.[2] The area covered by this eruption included the group of sunspots which was at the time three days before central meridian passage. A simultaneous wireless fade-out on wave-lengths below 50 metres was reported by the Cable and Wireless Co., starting at 11h. 8m. and lasting for 1¼ hours. It is significant that this fade-out only occurred in the channels of communication on the sunlit side of the earth. Communications through the opposite hemisphere were normal. The first of the magnetic storms followed approximately 26 hours later, beginning on March 24 at 13h. 45m., and a brilliant aurora was observed from the north of England the same evening.

The second period of activity began on March 27, when a bright eruption covering the same sunspot group was observed here at 17h. 10m. This was the brightest eruption of its kind so far observed with the Sherborne spectrohelioscope, and, like that of March 23, it was accompanied by a wireless fade-out lasting from 16h. 19m. to 18h. 30m. The magnetic storm of March 29, 16h., began just 48 hours later, and an aurora was again observed from British stations on the same evening.

This record of magnetic and solar activity, though possibly not yet complete, tends to confirm the evidence, recently summarized by H. W. Newton[3], suggesting a critical relationship between major chromospheric eruptions and 'great' magnetic storms, with an average time lag of 1½ days between the two phenomena. In neither of the above cases was it possible to observe the beginning of the eruption, so that the synchronism with the sudden beginning of the wireless fade-out could not be verified. In previous coincidences there has been an average interval of a few minutes between the beginning of the eruption and the onset of the fade-out, from which we may possibly conclude that the growing eruption must reach a certain limit of intensity or area, or of both combined, before the increase in ultra-violet radiation is sufficient to affect the ionosphere.

Intestinal Sugar Absorption and Phosphate Metabolism

IT has been shown in previous work that the selective absorption of sugars from the intestine of rats is strongly affected by iodoacetate[1]: after administration of this poison all hexoses are absorbed at the same rate. This has been interpreted as due to the fact that phosphorylation of sugars accelerates their absorption. It was shown that extracts of intestinal mucosa phosphorylize those sugars which are selectively absorbed; furthermore, that iodoacetate inhibits this phosphorylation[2] and that organic phosphate in the intestinal mucosa increases during sugar absorption[3].

It has now been found that absorption of any monosaccharide from isolated loops of the small intestine causes inorganic phosphate to enter the intestine, whereas absorption of sodium chloride or amino-acids has no such effect. Sugars which are not selectively absorbed also increase intestinal phosphates, but the change of concentration with time is different; with glucose the intestinal phosphate content is maximal already after 15 minutes and then falls off to about zero in about 1½ hours, whereas with xylose it rises slowly to about the same level in 45 minutes. After iodoacetate administration this difference disappears, and the phosphate content of the intestine after 45 minutes is the same for xylose and glucose. Also after adrenalectomy the reabsorption of phosphate during glucose absorption is suppressed. Thus entry and reabsorption of phosphate seems related to the selective absorption of sugars.

Experiments on the role of various endocrine glands which control intestinal sugar absorption are at present being carried out. It is also hoped that future work along the same line may throw light on the problem of phosphate metabolism in the bones. The results will be published in detail later.

Effect of Inversion of a Small Piece from the Fruit-Body of *Ganoderma lucidus* (Leyss.) Karst. growing *in situ* on the Trunk of *Casuarina equisetifolia*

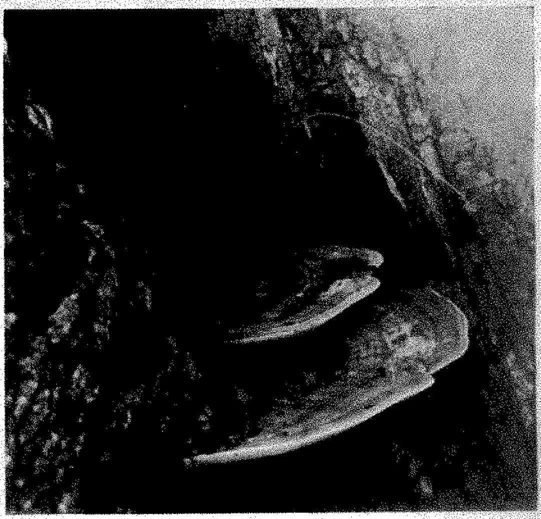

Fig. 1.

TWO SPOROPHORES OF *Ganoderma lucidus*, ONE GROWING ABOVE THE OTHER ON THE TRUNK OF *Casuarina equisetifolia*.

BRACKET-SHAPED sporophores of *Ganoderma lucidus* were growing on the trunk of an old tree of *Casuarina equisetifolia* in the Royal Botanical Gardens, Sibpur (Calcutta) in front of the superintendent's quarters on the bank of the Ganges. From each of the two sporophores, one growing over the other (Fig. 1), a narrow sector was cut out almost in the middle and inserted (on September 6, 1939) in the inverted position, that is, with the porous surface upwards in the cavity thus produced. It was found that in the course of nine days regeneration of the hyphæ began by way of stitching from two sides (Fig. 1). A number of interwoven hyphæ developed between the old sporophore and the new piece. The hymenial surface of the specimens was perfectly white in

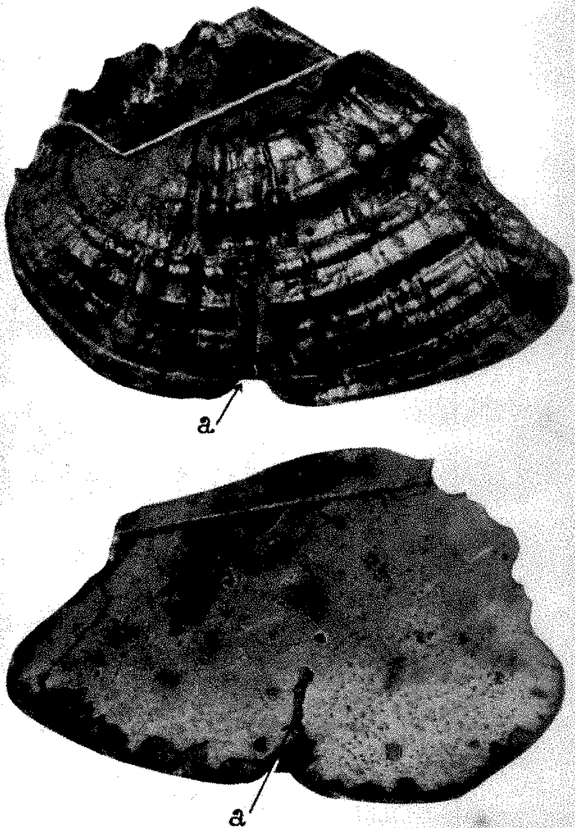

Fig. 2.

ABOVE—UPPER SURFACE OF THE SPOROPHORE OF *Ganoderma lucidus* SHOWING THE DEVELOPMENT OF LACCATE CRUST ON THE UPPER FACE OF THE CUT-OUT SECTOR AT *a*.

BELOW—HYMENIAL SURFACE OF THE SAME SHOWING FLANKING-OVER HYMENIAL GROWTH FROM TWO SIDES ON THE CRUST OF THE CUT-OUT SECTOR AT *a*.

September; copious spore-discharge continued for about two months, the adjoining areas of the trunk becoming dusted over with Ganoderma spores. Gradually, the lower surface turned pinkish and finally brownish with stoppage of spore-discharge by the following December. In the course of these three months the porous area on the upper face of the cut-out sector became gradually covered with the typical laccate crust-growth of the upper surface (Fig. 2, above) and its lower surface was at the same time flanked over with hymenial growth from two sides (Fig. 2, below). A section of the present upper face of the sector showed the typical thick-walled palisade hyphæ in close cluster with a number of brown shot-out spores here and there under the new crust (Fig. 3).

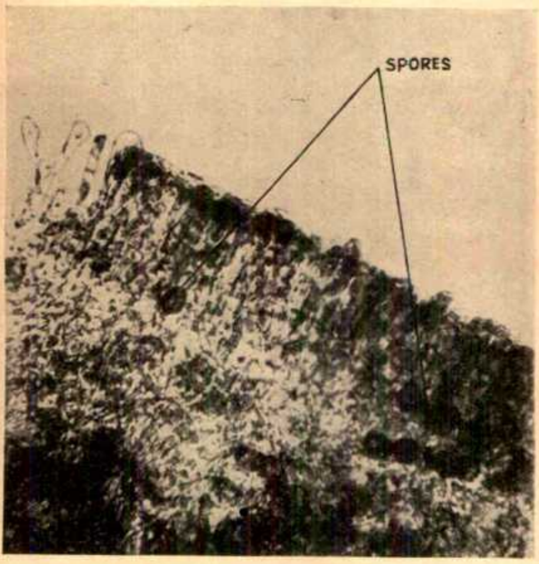

Fig. 3.

PHOTOMICROGRAPH OF A SECTION OF THE NEWLY DEVELOPED CRUST SHOWING THICK-WALLED PALISADE-LIKE HYPHÆ AND A NUMBER OF BROWN SPORES AT A LOWER LEVEL.

(Leitz objective No. 7. Eyepiece No. 75.)

This experiment lends support to the view recently put forward by Němec[1] and Lohwag[2] that the polarity in cases of some Polypores is convertible.

In another sporophore a narrow triangular gap was caused by removing a thin slice from about the middle; it was found that the gap was gradually bridged over in the course of about two months by numerous young hyphæ growing from two sides all over, except the outer thick crust.

For the photographs of Figs. 1 and 2 I am grateful to Dr. K. P. Biswas, superintendent of the Royal Botanical Gardens, Calcutta, and to Dr. D. B. Chatterjee.

Gynospore Formation in *Sequoia sempervirens*

IN spite of the intrinsic interest of the redwoods and mammoth trees of California their gametophytes and embryogeny were poorly known until recently. Lawson's[1] account of *Sequoia sempervirens* was unsatisfactory and incomplete and only a cursory reference by Arnoldi[2] was available for *S. gigantea*. Looby and I[3], however, described recently fertilization and proembryo formation in *S. gigantea* for the first time and also extended and amended Lawson's[1] account of these features in the redwood; while Buchholz[4] afterwards dealt with the embryogeny in both types. It is clear from the results recorded that development in these two trees is so different that they can no longer be retained in the one genus.

Except for the doubtful account by Lawson[1] of gynospore formation in *S. sempervirens*, no accurate description has yet been given of the early origin and development of the gynospores in either case. Collections have now been made to cover these phases and so complete the full life-history; and these phases also are quite different in the two plants. Details will be published in due course, but it seemed advisable to put on immediate record the unique condition found in *S. sempervirens*. A number of gynospore mother cells are commonly formed, of which up to eight (or more ?) may form tetrads. The members of a spore tetrad may form a linear row, but more frequently the gynospores are in compact groups of four, arranged symmetrically in one plane or in a tetrahedron, the whole being surrounded by a definite tapetum, usually of one cell layer. A transverse section of the ovule at this stage resembles a young pollen sac in a remarkable way.

In no other conifer is the sporangial nature of the nucellus so clearly shown. As these tetrads are only a little larger than the pollen tetrads this condition in the redwood is a further cogent argument against the continued use of the terms mega- and micro-spore for the spores of the conifers, with all that the use of these terms commonly implies.

Destruction of Cabbage White Butterflies by Birds

THE enormous numbers of 'Large Cabbage Whites' (*Pieris brassicæ* (L.)) which entered England last summer were preyed upon very frequently by birds, and this Department received many dismembered wings picked up in gardens, etc. The offspring of these immigrants have been much in evidence this month, and have also been destroyed in large numbers by birds.

Mr. A. H. Hamm, A.L.S., has kindly collected dismembered wings in a churchyard in east Oxford, and examination gives the following result:

FRONT WINGS COLLECTED OVER A WIDE AREA OF THE CHURCHYARD

	Male		Female	
	L	*R*	*L*	*R*
May 18	15	23	5	4
,, 19	4	6	6	7
,, 20	4	9	2	2
,, 21	4	1	–	3
	27	39	13	16

Hind wings are disregarded as it is often impossible to assign their sex.

COLLECTED ON BARE GROUND A FEW YARDS SQUARE IN THE CHURCHYARD

	Male		Female	
	L	*R*	*L*	*R*
May 18. 12.30 p.m.	6	4	8	7
,, 19. 1.10 p.m.	2	2	–	1
,, 20. 10.40 a.m.	1	2	–	1
,, 20. 2.10 p.m.	2	1	–	–
,, 21. 11.55 a.m.	5	5	2	–
,, 21. 4.15 p.m.	–	1	1	–
	16	15	11	9

The figures show that in four days birds had destroyed *at least* 54 males (the number of right front wings found), and 24 females (the number of left front wings found). A churchyard is not, of course, a place where females would congregate to lay eggs. The wings had been seized by the bases and pulled off; the bases are usually much rubbed, but in some cases a clear individual imprint of the bird's beak can be seen.

This is the case in 22 of the front wings and 10 of the hind wings; in most cases the imprint corresponds with the beak of a house sparrow, but in one at least it seemed to be that of a chaffinch (see Collenette, *Proc. Zool. Soc., Lond.*, Part 2, Pl. 1; 1935).

Binocular Vision

I NOTICE in the current number of the *Proceedings of the Royal Society* (vol. 128, p. 552) the question raised "Do two eyes see better than one ?"

I would refer those interested in the question to my note in the *Transactions of the Ophthalmological Society* (vol. 44, p. 183; 1924) which contains a simple demonstration of the fact that they actually do.

JOHN GRAHAM KERR.

Points from Foregoing Letters

C. F. Powell, A. N. May, J. Chadwick and T. G. Pickavance describe experiments on the scattering of fast protons of about 4 Mev. energy by some light elements. The scattered particles were registered by the photographic method, which enabled the energies of the scattered particles to be determined at the same time as their angular distribution. With neon as scattering element, two groups of scattered particles were found, one corresponding to elastic scattering, the other to inelastic scattering in which the neon nucleus had been raised to an excited state. Attention is directed to the possibilities of this method for obtaining information about the excited states of atomic nuclei.

The results of exposing photographic plates for five months at altitudes of 2,130 m. and 3,660 m. in India are described by D. M. Bose and B. Chowdhry. Various tracks were found, which are believed to be due mainly to mesotrons.

F. Weigert and J. C. Mottram describe three solid modifications of 3 : 4,benzpyrene which are distinguished by their fluorescence colours, green, yellow and blue, their relative stability and their solubilities. In the presence of cholesterol the intermediate stage of the blue form is stabilized temporarily. It is suggested that a similar stabilization occurs in cells which come into contact with benzpyrene. This would make available free energy for biological action.

Considerable differences in the behaviour of quartz-covered platinum wires and plain platinum wires immersed in flame gases, are believed by W. T. David and B. Pugh to confirm the view that a proportion of the newly formed tri-atomic molecules hold an excess of intra-molecular energy which cannot be handed over to the translational degrees of freedom. In virtue of this excess intramolecular energy, a much larger dissociation obtains in flame gases than in normal gases. A. S. Leah describes experiments which lend further support to this view and shows that the observed dissociation constant varies with the amount of excess intra-molecular energy.

It has been demonstrated by R. M. Barrer that rates of diffusion of hydrogen through palladium may be independent of current density. This implies that the metal just inside the ingoing surface is saturated, which in turn requires that the rate of transport across the ingoing interface no longer controls the rate of diffusion.

M. A. Ellison describes the bright chromospheric eruptions of March 23 and 27, together with the terrestrial disturbances accompanying them.

During sugar absorption from isolated loops of the small intestine, but not during absorption of sodium chloride or amino-acids, inorganic phosphate appears in the intestinal lumen, according to L. Laszt. With selectively absorbed sugars, rate of appearance and reabsorption are different from those with other sugars. Iodoacetate as well as adrenalectomy suppress the phosphate reabsorption.

S. R. Bose reports the result of cutting out a sector from a bracket-shaped Polypore, inverting the sector and replacing it. The upper and lower surfaces of the sector developed the characteristics of the adjoining tissue.

J. Doyle finds that *Sequoia sempervirens* forms, in the young ovule, up to eight groups of gynospore tetrads, frequently tetrahedral in arrangement. These are surrounded by a tapetum, the whole appearance, unique in conifers, resembling a young pollen sac in section.

The large numbers of the destructive large cabbage white butterfly destroyed by birds are shown by the wings found lying in gardens, etc. G. D. Hale Carpenter supplies data from Mr. A. H. Hamm proving that in a certain churchyard birds had destroyed in four days at least 54 males and 24 females.

RESEARCH ITEMS

Rostro-carinates in Africa

IN an important paper (*Trans. Roy. Soc. South Africa*, **27**, Part 3, 287–319), H. B. S. Cooke and J. Desmond Clark describe, among other discoveries, an industry located at the base of the Kalahari Sand of the Victoria Falls region. This industry, which is found on and in a carstone rubble bed below the sand, is probably of Lower Pleistocene age, and is composed of typical rostro-carinates, and nosed, and other implements made from chalcedony. The flakes exhibit, usually, unfacetted striking platforms and have been struck from cores showing signs of having been afterwards used as tools. The artefacts, which are unabraded, were evidently made upon an ancient land surface existing prior to the deposition of the Kalahari Sand. This discovery of rostro-carinates affords yet another instance of the occurrence in Africa of these specimens under conditions precluding their production by glacial and other natural forces, such as are invoked by some investigators to account for these implements when found in England.

Concealing Coloration Tested by a Sparrow Hawk

LLOYD C. INGLES made use of a young Californian sparrow hawk, *Falco sparverius*, to test its acuteness in discovering and feeding upon grasshoppers (*Trimerotropis*) under different conditions (*Condor*, **42**, 104; March–April 1940). Three experiments were devised to test the protective value of the colour, and the part played by movements of the grasshoppers in revealing them to the hawk. The author concluded that when all protective resemblance to the background was removed, the hawk readily found the grasshoppers even though they did not move, for they were dead. Individuals which did not move (dead) in grass were seldom seen and captured, even after the lapse of a much longer time. Movement in the grass was probably what led most frequently to an attack, but strikes made by the hawk at insects in grass were occasionally failures, whereas no failure was recorded on nearly twice as many strikes made on a non-protective background. The author suggests that sparrow-hawks and possibly other predaceous birds may occasionally obtain their prey by flushing it from cover where it is otherwise relatively safe because of its protective resemblance and motionlessness.

Alcohol and Mental Disease

THE January issue of *Mental Hygiene* contains an interesting paper on the use and effect of alcohol in relation to alcoholic mental disease before, during and after prohibition by Horatio M. Pollock, of the New York State Department of Mental Hygiene, Albany, New York. His paper is based on the study of 662 patients admitted to State hospitals during the periods 1920–23 inclusive and the years 1936–37 inclusive. The first period covered four years of comparatively effective prohibition and the second period two years under State and local regulation. The difference in the number of first admissions in the two periods is striking, the four years under prohibition yielding only 817 alcoholic first admissions or an average of 204 per year as compared with 1,703 or an average of 852 per year in the two years under the present licence system. The writer's principal conclusions are as follows: (1) The onset of alcoholic mental disease as a rule occurs only after several years of excessive drinking, which averages about twenty-two years in men and about fifteen years in women. (2) The average age of alcoholic patients on admission to a State mental hospital is approximately forty-five years. (3) Whisky and beer are the principal beverages that cause mental disease. Whisky either alone or in combination is by far the most potent factor. (4) Although alcoholic mental disease may result from regular or from periodic drinking, nearly 70 per cent of the writer's patients were regular drinkers. (5) In the great majority of cases a fixed habit of excessive drinking with frequent intoxication preceded the onset of mental disease. (6) Reduction of efficiency and loss of position commonly precede the onset of alcoholic mental disease. (7) Impairment of physical health frequently results from excessive drinking prior to the onset of mental disease. (8) A history of delirium tremens was obtained in 23·5 per cent of the 1920–23 group and in 29·4 per cent of the 1936–37 group.

Development of Aristapedia

THE recessive character aristapedia transforms the bristle on the antenna of *Drosophila melanogaster* into a tarsus. W. Braun (*Genetics*, **25**, 143–149; 1940) has transplanted imaginal disks from normal to aristapedia flies and vice versa at an early stage of development of the larva. Transplants of aristapedial disks into normal flies from 2½ days old led to the formation of leg-like structures on the antennæ, while transplants of normal disks into aristapedia flies led to development of normal antennæ. The author studied the combination of genes affecting leg structures with aristapedia. Both dachs and thickoid affected the type of tarsus-like antennæ of aristapedia flies. On the other hand, aristaless which reduces the normal antennæ had no observable effect on the aristapedia. These facts are taken to support Goldschmidt's view that the gene aristapedia shifts the development of the antennæ to an earlier stage, and this brings the antennal disks within the influence of a leg-evocating stimulus.

Genetical Studies in *Carica Papaya*

J. D. J. HOFMEYER (*Science Bull.*, 187, South African Dept. of Agric. and Forestry; 1938) describes his experiments on sex determination in the papaw. There are staminate, carpellate and hermaphrodite plants and intergrades in this species. The author suggests that the crosses carpellate × staminate and carpellate × hermaphrodite give 1 : 1 ratios for the parental types, while the cross hermaphrodite × staminate gives a ratio of 1 staminate : 1 carpellate : 1 hermaphrodite. A simple practical hypothesis of M_1m = staminate, M_2m = hermaphrodite, mm = carpellate, where M_1M_2 and m are allelomorphic is suggested. The genes $Y : y$ for flower colour are in one linkage group with M. The linkage values are M, $25Y$. The practical applications of the studies are discussed.

Oxides of Niobium

CHEMICAL and X-ray investigations of the niobium-oxygen system have recently been carried out by G. Brauer (*Naturwiss.*, **28**, 30; 1940). They indicate the existence of three oxides with the formulæ Nb_2O_5, NbO_2, and NbO. The pentoxide occurs in at least two different forms, one of which is obtained when niobic acid, precipitated from aqueous solution, is dehydrated at 600°–800°. Powder diagrams of this form show many lines. On heating it to higher temperatures, a new form with a different X-ray pattern is produced. The dioxide, NbO_2, is obtained by reduction of the pentoxide with hydrogen or niobium. Hydrogen, even at 1600°, is unable to carry the reduction further than the dioxide stage. Contrary statements in the literature can be traced to the use of impure hydrogen. According to Goldschmidt, NbO_2 should possess the rutile structure, but powder diagrams of the purest dioxide show weak lines in addition to those corresponding with this structure. Apparently the structure is closely related to the rutile type, though not identical with it. When powdered niobium is heated with the dioxide to 1750° in an atmosphere of argon, the monoxide NbO is obtained. It is a grey solid with a metallic appearance, and crystallizes in the cubic system.

Remagnetizing Magnets used in D.C. Meters

THE commonest cause of D.C. meters registering outside allowable limits is deterioration of the strength of the field magnet. The usual error curve for a meter thus affected shows a rapidly falling line from 1/20 to full load; so even if the gearing ratio be adjusted to be correct at half load, the full load error will still be slow and the light load error fast. This follows since the driving torque is proportional to the magnetic flux density and the braking torque is proportional to the flux density multiplied by speed; thus the maximum differences of registration are at the opposite ends of the meter range; the full load error will still be slow and the light load error fast. In the *Electrical Times* of May 16, a cheap and efficient method of remagnetizing the magnets is described by R. Callender which should lead to appreciable economies in service. The meter element is taken out of the case and the register removed. A large current is then 'flashed' round the magnet; the field strength being now too great, it is reduced slightly to near the normal working value. This is accomplished by passing instantaneously a reduced current in the reverse direction. This is effected by inserting a suitable copper fuse in the circuit and proceeding to 'flash' as before. The meter element must then be laid aside for a month or two before it is reassembled. In order to bring the magnet field strength to normal working value, the magnets are further artificially aged by passing a short-circuit current through the meter. This should be done twice when the meters are connected in series for test, suitable fuses being used. The first operation reduces the field strength by about two per cent and the next by about a half per cent. Subsequent short circuits should have little, if any, effect.

Absorption of Hard Cosmic Rays and Mesotron Decay

IT has several times been suggested that the observation that the absorption of hard cosmic rays is less in a medium of low density such as air than in the same mass of a denser material may be explained by the spontaneous decay of the mesotron into an electron. The loss of mesotrons by decay becomes appreciable when the time taken for the mesotron to traverse the absorber becomes comparable with the mean life of the particle. The experimental evidence in this sense has been made much more definite by the work of B. Rossi, N. Hilberry and J. B. Hoag (*Phys. Rev.*, **57**, 461; 1940). The vertical intensity of hard rays was measured by a counter system containing 13 cm. of lead. The intensity was measured at several heights up to 4,300 metres, and the absorption in a thick graphite block placed above the counters was measured at the higher station and thus compared directly with that of air. Carbon was chosen as having an atomic weight and number close to that of air; the effect of scattering and of showers was carefully considered. The results showed the excess absorption referred to above, and the average life of the mesotron was found to be about 2×10^{-6} sec. It was not found possible to establish the increasing range of the mesotrons predicted by theory as the mesotrons become more energetic on filtration through the atmosphere; but it is not certain that a sufficient increase in mesotron energy by filtration actually occurs in the range studied. E. Fermi (*Phys. Rev.*, **57**, 485; 1940) finds theoretically that the loss of energy of any fast particle due to ionization of the atoms in its path is less in a dense than in a rarefied substance. This effect is due to the screening effect of the polarization of surrounding molecules. It is in the same sense as the effect attributed to the decay on the mesotron in cosmic rays. A calculation on classical lines indicates that the effect is large at very high particle energies. At moderate energies the effect is not sufficient to explain the results obtained by Rossi, Hilberry and Hoag, which are therefore probably correctly attributed to mesotron decay.

Electric Potential Gradient of the Lower Atmosphere

MEMOIR No. 8 of the Commonwealth Solar Observatory, Canberra, describes the results of the potential gradient observations made at Mount Stromlo during the years 1933–38. The electric potential gradient of the lower atmosphere at this station has now been the subject of continuous study for twelve years. C. W. Allen, in discussing the latest results, deals chiefly with the diurnal variation and its relation both to local and to world-wide factors. The local diurnal variation consists mainly of a sharp increase of gradient at sunrise to a maximum 5 hours later, and then a gradual decrease until the next sunrise, interrupted only by a slight depression at the intervening sunset. Its effect on the observations is nearly eliminated by examining only days of "continuous wind", that is, days on which the wind is constant in direction with a minimum velocity 5 m.p.h. for more than twenty-four hours. Correction of the Canberra observations for the local variation gives a "world variation" agreeing well both in phase and amplitude with ocean observations: a sharp minimum of about 84 per cent of the mean value occurs at 4h. U.T. and is followed by a slow rise to a maximum (120 per cent of the mean value) which is retarded from 18·5h. U.T. in January to 20·5h. U.T. in July. The curve showing the annual variation at Mount Stromlo indicates that the gradient is at a minimum in May and at a maximum in August; the elimination of local variations, however, removes both these, and the resulting curve is featureless. There is no evidence of any secular variation with the sun-spot cycle.

BONE AND STONE INDUSTRIES OF EARLY MAN IN CHINA

SINANTHROPUS

FOR the first recognition of the fact that Sinanthropus had made and used implements of bone the archæological world is indebted to the Abbé Breuil. Before 1930, it was not known that the Choukoutien cave, in which the osteological remains of Peking man had been discovered, was an archæological site; but in that year Dr. Breuil recognized that the base of the antler from the cave, shown to him in Paris, had been burnt and fashioned into a tool by blows of a stone implement. Further discoveries of quartz flakes and burnt bones followed, and were in turn succeeded by the discovery of the rich cultural layer at the base of the Kotzetang in 1931. A visit to the site in that year by Dr. Breuil led to the identification of a large number of tools fashioned of bone or antler; and as these were not universally accepted without question, he was invited to make a further and more detailed study of them, of which the results are now made available*. It is to be noted that material found later than 1934 is not included in the report.

For the present purpose, the significant facts of the Choukoutien site may be summarized as follows: Locality 1, a completely collapsed cave filled with debris to a depth of 50 metres, shows five horizons each of which yields evidence of Sinanthropus. At the base of Level 4 is the famous cultural layer in Kotzetang. Three further sites only have yielded cultural remains of Sinanthropus age: Locality 13, older than Locality 1, but only a few flakes and a single but fine chert artefact; Locality 15, possibly connected with the eastern slope of Locality 1 and containing a remarkably rich and advanced lithic industry; and Locality 4, still under excavation and yielding, at present, nothing but a few atypical broken stones.

No remains other than those of Sinanthropus occur from top to bottom of the deposits of Locality 1, and there is, therefore, no valid reason for assuming the existence of another inhabitant of the cave, as do some prehistorians. Nor does the predominance of cranial remains support the suggestion of the practice of head-hunting, which belongs to a more advanced stage of culture, while in the only certain prehistoric example known (Ofnet, Bavaria) in all the specimens, as a rule young or feminine, the first two cervical vertebrae are retained and show marks of having been sectioned by a flint. At Choukoutien only one atlas, loose, has been found. The explanation here offered is that it is a deformation, an aberrant evolution from reverence for the family skulls as ensuring ancestral protection.

Certain criteria distinguish animal action on bones from that of man. The most likely to give rise to uncertainty are the hyæna, the beaver and the porcupine. The crushing action of hyæna jaws is difficult to distinguish in effect from the hammer-anvil blow of man, though a hyæna never splits a bone lengthwise. A single bite by a beaver or porcupine may make a double or single incision which resembles a notch made by a metal tool, while their action in gnawing the end of a bone may look like a point chopped by man. This is the origin of the so-called 'worked' elephant bones of Piltdown.

From the point of view of the toolmaker, three stages in fossilization are to be distinguished: (*a*) when still fresh the bone breaks cleanly and can be used readily for implements; (*b*) in the first stage of fossilization disintegration predominates over mineralization, bone is brittle, tends to crumble and has an irregular fracture; (*c*) complete fossilization renders it capable of being broken cleanly and sharply, but the outside and inside being usually of a different colour, breaks can easily be seen. The bones found at Choukoutien all belong to Stage (*a*).

In considering the industries of the earlier palæolithic periods, while it is admitted that, in addition to stone, man must have used wood, which has perished, it is usually overlooked that in bone man had at hand a convenient and adaptable material most of which also must have disappeared. The bone industry was first developed but was not invented in Upper Palæolithic times.

From the days of Sinanthropus, man has used horns of antelope, gazelle, goat and young ibex (ox horns being too big) antlers and stag-horns, skulls, jaw-bones, long bones, whole or broken, fragments of diaphyses, and flakes, short bones, chiefly astragals, carpus, tarsals and phalanges, vertebrae, ribs, iliac bones and shoulder blades, which in the Upper Palæolithic show evidence of having been used as shovels or scrapers.

Thus bone was used whenever a hard substance was needed, exactly like any stone, from the dawn of human toolmaking. The facts at Choukoutien confirm exactly observations at Castillo, Santander, Spain, as against the contention that the palæolithic bone industry is confined to the Upper Palæolithic and some rare Mousterian objects.

The material used at Choukoutien and identified includes horns and skulls of deer and ruminants, jaw-bones and teeth of deer, wild boar, fragments of elephant ivory, maxillæ of Carnivora (hyæna, leopard, tiger, bear), body and leg bones, including shoulder blades, humerus, radius, femur and tibia of deer, horse, rhinoceros, hyæna, bear, etc. The anatomical origin of a large number of flakes is difficult to determine.

An interesting and important point to emerge is that the state of the deer antlers points to a seasonal migration among them. All except two of the antlers of Pseudaxis are attached to the skulls and must have been so born when the animal was killed, while in Euryceros the majority of antlers have been shed. The antlers being shed at the beginning of winter after the rutting season, evidently the Euryceros migrated from the highlands to avoid the cold and occupied the country of the Pseudaxis, which retired before them until they retreated in the following year. The absence of half-grown antlers suggests that during the five months until the end of summer, Sinanthropus either left his cave or did not eat animals.

THE UPPER CAVE

The Upper Cave at Choukoutien, when discovered in 1930 during the search for Sinanthropus remains, was considered of relatively little importance; but when it was fully excavated in 1933–34, it was found to be of unique character in Chinese prehistory. In it were found not only artefacts of an Upper Palæolithic culture, but also the skeletal remains of a number of individuals representative of Upper Palæolithic man in China, who hitherto had been unknown. The results of the excavation of the cave are to be described in a series of monographs, of which that dealing with the archæology by W. C. Pei is the first to appear*.

---

* Bone and Antler Industry of the Choukoutien Sinanthropus Site. By Henri Breuil. Translated by Miss M. E. Boyle. *Palæontologia Sinica*, N.S.D., No. 6, Peking, 1939, pp. 40+26 plates.

The Upper Cave, previous to excavation, was completely covered by the superficial soil of the hill and filled with deposits, consisting of a grey loam mixed with fragments of collapsed rock. This was completely removed down to the red and hard breccia of the Choukoutien formation, in which further excavation would have been unprofitable. The cave consists of an upper room, a lower room and a lower recess, a narrow cavity three metres long and one metre wide, forming the lowest part of the cave. Five cultural layers were distinguished. It is possible that the Lower Room, in which human remains, including three complete skulls, were found, may have been a burial place only and not a dwelling site. In the lower recess an accumulation of animal bones and skeletons alone was found.

Occupation lasted up to the complete filling of the upper room. The Upper Cave industry is characterized by a poorly developed, or at least poorly represented, lithic industry in which chert, sandstone, quartz, all foreign to the site but found in the vicinity, are in use. The types of implements include scrapers, choppers, as well as pebble implements. A notable feature is the use of personal ornament-perforated pebbles, stone beads with large perforation and one ground surface. The bone, antler and shell industries, mostly reserved for ornamental purposes, are most characteristic, and being usually left in natural shape are typical of a 'primitive' industry. A remarkable find is a bone needle, such as was not known hitherto to have occurred in China before Neolithic times. The technique of polishing is to be observed on a deer antler and the jaw-bone of a Sika deer.

As a whole, the Upper Cave industry is clearly ranged within an Upper Palæolithic stage, but on comparison with its European equivalents it shows a mixture of relatively primitive and relatively advanced characters. It is likely that these artefacts represent an isolated culture of their own, indebted in part to a northern 'palæarctic' culture, in part to a Pacific culture sheet extending from Malaya to Manchukuo. It may on palæontological and archæological grounds be regarded on the Eastern equivalent of the Western Late Magdalenian.

FOOD PRODUCTION WITHOUT ARTIFICIAL FERTILIZERS

By Ysabel Daldy

AN ACCOUNT of a valuable experiment in the feeding of schoolboys on vegetables and fruit grown from soil manured exclusively by humus is published by Dr. G. B. Chapman, of the Physical and Mental Welfare Society of New Zealand, Incorporated (Burnock Publications, Auckland, 1939). The locale of the experiment is the Mount Albert Grammar School hostel, the subjects being some sixty boys, teachers and staff. At the time of the inception of the experiment (1936), the dietary at the hostel was liberal, being well above the customary standard for boarding-schools; yet the boys consistently suffered (as was the case in other New Zealand schools and institutions) from colds, catarrh, septic tonsils, epidemics of influenza, dental caries and other preventable complaints. The whole of New Zealand's food supplies are grown from soils manured by the ordinary chemical fertilizers.

Dr. Chapman opened his campaign in 1936 by delivering a few short lectures to the resident teachers and boys, advising the growing of the hostel's fruit and vegetables from soils to be treated by properly prepared humus. He was successful in arousing the interest of the teachers, the boys, the matron and the staff. The reform was put in hand and the change-over made from 'chemically grown' fruit, salads and vegetables to the 'naturally produced' foods now in use at the hostel. At the present time, approximately an acre of land is under cultivation for the benefit of the hostel, to the soil (black volcanic) of which no chemical or artificial fertilizers of any kind have been applied. The area in question is supplying the greater proportion of the green vegetables, salad-greens, pumpkins, kumaras, root-vegetables and fruit required by a household of some seventy-seven persons. The following general report of progress in health since the time of the change-over has been submitted by the matron of the hostel (pp. 4–6, "Menus and Recipes", Chapman and Lowe, 1939):

"The first thing to be noted, during the twelve months following the change-over to garden produce grown from our humus-treated soil, was the declining catarrhal condition among the boys. Catarrh had previously been general and, in some cases, very bad among the boys. In specific cases the elimination was very marked and in many cases complete. There was also a very marked decline in colds and influenza. Colds are now rare and any cases of influenza very mild. Coming to the 1938 measles epidemic, which was universal in New Zealand, the new boys suffered the more acute form of attack; while the boys who had been at the hostel for a year or more sustained the milder attacks, with a much more rapid convalescence.

"During the past three years there has been a marked physical growth and development during terms of heavy school work and sport [actual heights and weights are quoted]. In some cases boys go through a period of indisposition for several weeks after entering the hostel. This would appear to indicate that the method of feeding causes a certain detoxication period which, when cleared up, does not return. Excellent health gradually ensues in all cases, and is maintained. There are fewer accidents, particularly in the football season, which would possibly indicate that the foods in use contain the optimum amount of minerals and vitamins, thus ensuring a full development of bone and muscle and a greater resiliency to fractures and sprains. The satisfactory physical condition described is maintained during periods of rapid growth and development of mind and body. Constipation and bilious attacks are rare. Skins are clear and healthy, while the boys are unceasingly active and virile.

"Since the change to naturally grown garden produce, the periodical reports in regard to the boys' dental condition have been more than gratifying." This point needs emphasis, as New Zealanders continue to show a poorer dental condition than is the case in most other countries of the world. In connexion with present-day examinations of young men volunteering for service in the War, the Hon. W. E. Parry, Minister of Internal Affairs, has published the fact (*New Zealand Herald*, October 2, 1939) that forty per cent of the recruits are found to be temporarily unfit through defective teeth.

Dr. Chapman has now interested the Government of New Zealand in the results he is obtaining from a dietary inclusive of naturally grown fruit and vegetables; and the Mount Albert Grammar School hostel experiment will in future be continued under the auspices of the New Zealand Health Department.

ORIGIN OF THE VERTEBRATE COELOM

By H. Barraclough Fell,

(Shirtcliffe Fellow, University of New Zealand)

RECENT years have witnessed a series of fundamental changes in our ideas on embryology, these changes being the expression of what had formerly been a growing mistrust of some of the generalizations of the nineteenth century. Thus de Beer[1], in the course of a convincing essay, set forth strong evidence to show that the theory of recapitulation cannot be accepted in its original form. Again, Oppenheimer[2] has recently reviewed the results of research on the earlier stages of development, and her conclusion is that ". . . the doctrine of the absolute specificity of the germ-layers as enunciated in the last century must be abandoned". So early as 1894, Garstang[3] had presented evidence leading him to believe that the ancestor of the chordates could be found in an animal closely approximating to the present larval forms of echinoderms. One important consequence of Garstang's work in this direction is that it has led to the recognition of the fact that evolution can act on the earlier stages of development; the original recapitulation theory supposed that evolution worked only on adult forms, tacking on, as it were, additional phases at the end of ontogeny. The echinoderm theory has received ever-increasing attention, until now it may be regarded as the most important attempt to solve the problem of the ancestry of the chordates.

The theory in its present form, however, seems to suffer from one serious drawback, in that it supposes that the schizocoel of vertebrates arose from the enterocoel of the echinoderm larva. It has been urged that the formation of the anterior coelomic pouches from the archenteron in Amphioxus provides evidence of the enterocoelous nature of the original vertebrate coelom. Against this it must be adduced that all known vertebrates have now a schizocoel, and that it is only Amphioxus and its related forms that have an enterocoel. As Amphioxus is in so many ways highly specialized, there can be no safe ground for believing that its mode of derivation of the coelom is primitive. Furthermore, there are other groups of invertebrates, notably the annulates, in which there are strong features of resemblance to the vertebrates, and at the same time a schizocoelous development of the coelom.

It is clear that the above objection applies only so long as we regard the coelom of echinoderms as being necessarily an enterocoel—and, up to the present, there appears to have been no suggestion that this may not be the case. Now, the formation of hollow structures by derivation from pouches does not on the face of it appear to be primitive. Rather it would seem to be a later 'short-circuiting' of some more primitive method which must have involved first the formation of a mass of tissue (in this case mesoderm, derived from endoderm of the archenteron), and secondly the excavation therein of a cavity (in this case the coelom). In the same way it has already been suggested by other workers that the invaginative method of formation of the endoderm and its enclosed cavity the archenteron may be a later short-circuiting of a more primitive scheme in which there first arose a solid mass of endoderm (by migration, delamination, or some other means), and then later the archenteron was excavated in this mass. Invagination in the case of the latter instance, and pouch-formation in the case of the former, are to be regarded as later products of evolution, enabling the final result to be attained in shorter time. One reason for being unable to regard as primitive the pouch method of formation of the coelom is that it is difficult to imagine the incipient stages of such a process, unless we postulate some such previous development as has been outlined.

So far, no practical evidence has been forthcoming to confirm that the enterocoel of the echinoderms is not the only type of coelom found in that group, nor has there been any concrete evidence to show that the echinodern enterocoel may not be primitive. However, in a paper now in the press[4] it will be shown that the coelom actually does arise by splitting in the mesoderm in a New Zealand ophiuroid. The fact that this species (as yet unidentified) has an unusual development was first discovered and recorded by Kirk[5] in 1916, but the schizocoelous origin of its coelom has only recently come to light. This unexpected feature led me to consult a paper by Russo[6] published as long ago as 1891, in which he claimed to have found that the coelom in the ophiuroid *Amphiura squamata* arose by splitting in mesenchyme. Owing unfortunately to his inaccurate description and figures, Russo's results were ignored by subsequent workers; but actually he was never proved to be incorrect. His statements, of course, accorded ill with the recapitulation theory then holding sway. I am at present engaged upon a re-investigation of the development of *A. squamata*, and the preliminary results seem to confirm that Russo was indeed right in assuming the schizocoelous origin of the coelom, though in other matters he was mistaken. Thus in one echinoderm at least, and probably in two, there is a schizocoel. In all likelihood the same will be found to be true of other species too.

There are some relevant facts which must be mentioned here. Both Amphiura and Kirk's ophiuroid are species with yolky eggs. In both species the development is shortened. Thus Amphiura has only a vestigial larva within the bursa of the parent, while in Kirk's species there is no larval stage whatever, the development being direct. The latter species, unlike Amphiura, is not viviparous.

It may be argued that the presence of yolk material in the eggs of these two species, and the viviparous habit of the former, render them too specialized to be regarded as being capable of giving rise to anything else in evolution. Against this the following facts must be considered:

(1) Yolky eggs are very common in echinoderms. The fact that the development of so few yolky species is known may well have given us an incorrect idea of echinoderm embryology in general.

(2) Kirk's ophiuroid is not viviparous, and yet has a more direct development than Amphiura, which is viviparous. Therefore viviparity cannot be regarded as a cardinal factor in producing direct development, unless we suppose that Kirk's species was formerly viviparous and then lost the habit.

(3) Most of the lower vertebrates have more or less yolky eggs, together with (invariably) a schizocoelous coelom. This fact is to be considered in relation to the same conditions prevailing in the two echinoderms cited.

(4) Amphioxus, on the other hand, has a non-yolky egg, and, as might be expected from the foregoing, has an enterocoelous coelom.

(5) The widespread occurrence of yolky eggs in so many different classes renders it doubtful whether yolk really is a specialization after all. In any event, the heavily yolked reptilian egg is held to have given rise to the mammals (in whose eggs the yolk is so reduced). Therefore it should not be difficult to imagine an echinoderm larval form, with yolk-material in its tissues, giving rise to other forms.

There is a difficulty in that it appears, from the limited evidence at present available, that suppression of the larval stage tends to accompany the presence of yolk. It is not clear as yet, therefore, whether an echinoderm larva can itself possess a schizocoel, but it has been shown that a schizocoel can occur in the life history. In my view, the significance of the association of yolk in echinoderms and chordates with a schizocoelous development of the coelomic cavities is this: the presence of inert food-material in the endoderm tends to retard the changes of organization of the latter. The yolk for physical reasons makes the cutting off of enterocoelous pouches an excessively slow process. Hence the more primitive method is reverted to, by which the coelom arises as a schizocoel in a mass of mesoderm.

Since writing the above, it has been found that in the embryo of *Ophiomyxa brevirima* the region of the future coelom is first occupied by an extensive zone of solid mesenchyme. The obvious similarity to the condition in *Amphiura squamata* and in Kirk's ophiuroid leaves little doubt that the coelom in this form must also arise as splits in the mesenchyme mass. Here, too, the embryonic tissues are laden with yolk. A fuller account will be published elsewhere.

POST-GLACIAL VEGETATION OF ENGLISH FENLAND

A STRATIGRAPHICAL sequence of lower peat, fen clay, upper peat and upper silt is characteristic of the whole of the southern part of the Fenland. The corresponding sequence of post-glacial vegetation successions throughout the area and their correlation with archæological horizons is described by H. Godwin (*Phil. Trans. Roy. Soc.*, **230**, No. 570, Feb. 1940).

Evidence from pollen analysis methods shows that birch, which along with pine originally dominated the area in Pre-boreal times, was replaced in the Boreal period by pine; whilst extensive elm and oak woods developed with an undergrowth of hazel and with alder and lime in favoured places. These forests were occupied by Tardenoisian people, as evidenced by microlithic flints from weapons and tools. Oak, alder and lime predominated during the succeeding wetter Atlantic period, and the post-glacial forests reached their maximum development, affording shelter for late Mesolithic and Neolithic peoples.

Within the Neolithic period the Fenland area became generally water-logged and fen peat began to accumulate, embedding the tree bases and leading to their destruction and to the transition to a sedge fen with wooded tracts of alder, willow and birch. Drier Sub-boreal conditions led to renewed development of woodland, to be succeeded by extensive invasion by the sea and the conversion of the whole area into a brackish lagoon. The deposition in this shallow lake of silt and clay gave rise to the thick deposits of fen clay overlying the lower peat.

In the Bronze Age, freshwater fen was re-established and a new mantle of peat formed. Towards the end of the period dry fen woods, across which pre-historic man passed freely, had once more extended across the full width of the fens. At 500 B.C. the colder and wetter conditions made the area uninhabitable for, in contrast with the Bronze Age, no trace of Iron Age man has been found.

The effect of climatic deterioration was heightened during the Roman period by a further phase of marine invasion giving rise to extensive coastal salt marshes of silt and raised river banks which penetrate far into the peat country. Romano-British agriculture spread along the silt banks of the river channels, and the first drainage operations date from this period. Between then and the effective drainage of Fenland in the seventeenth to the nineteenth centuries no trace is available of human occupation. The present change in relative land and sea-levels points to a further marine invasion.

The New Australian Mud-fish

P. L. SCLATER, F.R.S., secretary of the Zoological Society, describes and illustrates the newly discovered Australian mud-fish, basing his account on a paper sent to the Zoological Society by Mr. Gerard Krefft, curator of the Australian Museum, Sydney, who had named the fish *Ceratodus forsteri*. The general resemblance of the fish to Lepidosiren is remarked upon, and it is said to be so common that it is known as the "Burnett" or "Dawson salmon", from the two Queensland rivers in which it is principally found.

In conclusion, Mr. Sclater hopes that "this short notice may have the effect of calling the attention of some of the colonists of Queensland to the wonderful nature of this relic of the Devonian epoch that is now swimming about beneath their noses, and that they will cease, for the present at least, to kill it and eat it as 'salmon'. Any specimens that may 'rise to their fly' should be carefully kept out of the way of the cook, preserved in alcohol and transmitted to the British Museum or some other scientific institution".

Fizeau's Experiments on "Newton's Rings"

PROF. G. CAREY FOSTER, F.R.S., compares the wave-lengths of the sodium doublet as determined by Ångström with observations made by Fizeau by the method of Newton's rings.

Fizeau produced Newton's rings by means of a convex lens and a plane glass illuminated "by the yellow flame of spirit of wine containing a little common salt". It was found that, on separating the lens from the glass, the rings contracted, disappeared at the middle, and were replaced by new rings. In this way, nearly 500 rings were counted, after which rings ceased to be visible; then after a period, a further 500 rings became visible again, and so on. The explanation is that the yellow light used consists of two parts of slightly different refrangibility. Each part is capable of producing a set of rings, and when they are put together, they nearly, but not quite, fit each other. The effect can be explained on the "undulatory theory" of light, and gives results in good accord with those derived from Ångström's wave-length measurements.

The Natural History Collections

IN 1858, a memorial on the organization of the British Museum Natural History Collections was submitted to the Chancellor of the Exchequer by a group of four zoologists and five botanists. Nothing was done at the time, but the subject having again come before Parliament, the memorial was printed in NATURE in full, and readers, especially botanists, were asked to communicate their views to the Editor.

AT a meeting of the German Chemical Society on May 23, A. Baeyer and M. Emmerling reported on the transformation of isatin into indigo. When treated with phosphorus in "chloride of acetyle or of phosphorus", isatin forms indigo-blue and indigo-red.

THE council of the Society of Arts has awarded the Albert Medal to M. F. de Lesseps, "for services rendered to arts, manufacturers, and commerce, by the realization of the Suez Canal".

MR. JOULE has been elected to the Section of General Physics of the Paris Academy of Sciences.

FORTHCOMING EVENTS

Monday, June 10

ROYAL GEOGRAPHICAL SOCIETY, at 5 p.m.—E. J. Wayland "Forest versus Desert in Eastern Africa".

Tuesday, June 11

ROYAL ANTHROPOLOGICAL INSTITUTE, at 5 p.m.—E. J. Wayland: "Some Aspects of Uganda Prehistory".

ZOOLOGICAL SOCIETY OF LONDON, at 5 p.m.—James Fisher: "The Status of the Fulmar in the British Isles". A Symposium on Taxonomy and Palæontology (J. A. Moy-Thomas: "Problems of Palæontological Classification"; E. B. Ford: "Palæontological Classification from the Geneticist's Point of View"; Dr. L. R. Cox: "Problems facing the Invertebrate Palæontologist").

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

INSTRUCTOR IN MECHANICAL ENGINEERING WORKSHOP PROCESSES AND PRACTICE—The Secretary for Education, County Education Offices, Northampton (June 12).

TECHNICAL ASSISTANTS (MECHANICAL ENGINEERING) IN THE DIRECTORATE OF AMMUNITION PRODUCTION—The Secretary, Ministry of Supply (S.E.3.b), Adelphi, W.C.2 (quoting Appts. 034/S.E.3.b) (June 12).

PROFESSOR OF MATHEMATICAL PHYSICS—The Secretary and Bursar, University College, Dublin (June 15).

HEAD OF THE CHEMISTRY DEPARTMENT—The Clerk to the Governors, Technical College, Normanton Road, Derby (June 15).

ASSISTANT LECTURER IN MECHANICAL ENGINEERING—The Principal, Technical College, Kingston-upon-Thames (June 18).

LECTURER IN EDUCATION—The Acting Secretary, University Court, Glasgow (June 20).

A METALLURGIST OR A METALLURGICAL CHEMIST at the Medway Technical College, Gillingham—The District Education Officer, Fort Pitt House, New Road, Rochester, Kent (June 22).

LECTURER (MAN OR WOMAN) IN THE DEPARTMENT OF PURE AND APPLIED SCIENCE, FOR BIOLOGY, ANATOMY AND PHYSIOLOGY—The Registrar, Loughborough College, Loughborough, Leicestershire (June 22).

GRADUATE ASSISTANT MASTER TO TEACH MATHEMATICS AND SCIENCE—The Principal, Technical Institute, Beckenham Road, Beckenham (June 24).

ASSISTANT ENGINEER TO THE CENTRAL ROAD BOARD, BARBADOS—The Secretary, Central Road Board, Bridgetown, Barbados (July 13).

EDUCATION LECTURER AT THE PORTSMOUTH TRAINING COLLEGE—The Registrar, Municipal College, Portsmouth.

THE WAR EXTENDED

SIGNOR MUSSOLINI'S decision of June 10 has inspired the contempt of all freedom-loving peoples. That two men are able to decide the fate of about a hundred and fifty million people, and challenge, directly or indirectly, the peace and prosperity of the rest of the world with little or no reference to other authority, is perhaps the greatest blow to human dignity in history. But this is not the time for recrimination and criticism. The challenge must be met now.

On the same day, Mr. Duff Cooper, Minister of Information, spoke of this new tragedy, pointing out that there is so much that we all like and admire in Italy and the Italian people. All scientific people will contribute to this view. It is scarcely necessary to mention the fruitful fields for archæological and historical studies offered by that country, the first marine biological station at Naples, the important contributions to the mathematical and physical sciences made by Italy over a period of centuries. Yet it is a sad reflection on modern civilization that we must now anticipate an "increase in the number of ruins for which Italy has long been famous". Much, far too much, of Europe is already in ruins ; there is not the slightest reason or excuse for opening out the vista of this hideous carnage. "No war has ever been declared with so little provocation as this. Italy had no quarrel with Great Britain or with France, and had made no claim which had been refused." Every problem could have been solved by scientific and honest debate.

M. Reynaud, on this same sad day, asks : "How shall we judge this act ? France has nothing to say. The world which is looking on will pass judgment." The lovers of freedom and of democratic government have passed their judgment in no uncertain terms. The highest moral authorities in the world, including the Pope and President Roosevelt, had repeatedly tried, but in vain, to prevent the extension of war, which is opposed to all ethical principles and to human solidarity.

Two great democracies, two great Empires, are fighting for their freedom and that of other countries—indeed of the world. After all else had failed, they were compelled to meet force with force. To those "evil things" which they have been fighting for ten months are now added more evil things. But great inspiration is forthcoming to those two democracies from a third. There has been no doubting the moral attitude of the United States since hostilities began ; but on the day of Italy's declaration, President Roosevelt, at the graduation exercises of the University of Virginia, spoke emphatically of Italy's scorning "the rights and securities of other nations".

"On this tenth day of June 1940," he said, "from this University, founded by the great American teacher of democracy [Thomas Jefferson, third president of the United States], we send forward our prayers and our hopes to those beyond the seas who are maintaining with magnificent valour their battle for freedom." The Americans have now seen beyond any shadow of doubt the ascendancy of the philosophy of force in country after country where free institutions and individual liberty to search for truth and to express opinion were once maintained ; where control of machines was retained in the hands of mankind as a whole. "Neither those springing from that stock nor those who have come hither in later years can be indifferent to the destruction of freedom in their ancestral land across the sea", the President said.

For years NATURE has striven hard for intellectual freedom in thought, word and action. We can never subscribe to any theory of nationalism in science; and therefore men of science can now look with deep satisfaction on the quick passing of the isolationist policy so recently advocated by certain groups of Americans, but now so clearly repudiated by their President.

The British and the French are not nations fighting nations, but freedom-loving peoples actively opposing the forces of evil and falsehood. In this hour of need it is a comfort to know that the United States is now to "extend to the opponents of force the material resources of this nation".

Unity in the common cause has been achieved within the British Empire and within the French Empire, and also between the two. Movement towards the achievement of such unity throughout the democratic States of the whole world is increasing in momentum, a movement in which science is playing an important part. In the leading article in NATURE of May 25, p. 796, attention was directed to the brilliant contributions to our war effort that many men of science of the Allies are making in the Fighting Services and research organizations immediately connected with them, to say nothing of the many scientific workers and teachers carrying on at the home front. (Alas, the work of many others in Poland, Norway, Holland and Belgium has been immobilized by the brute force which has temporarily overcome them.) But now to these efforts will be added much from our colleagues in the United States.

When "the control of machines was retained in the hands of mankind as a whole", untold benefits accrued, but under the system of force in the hands of irresponsible conquerors, the machine becomes master, with mankind a servant and victim. It cannot be denied that science has been a major element in forcing such a grievous issue resulting in this holocaust. But the conscience of science is clear. She offers man a rope to skip; she cannot be blamed if he chooses to hang himself with it. On the other hand, science is willing, nay eager, to assist him along the path of prosperity and happiness which she has helped to provide.

Thus, when Great Britain declared war on Germany, the voice of science was raised. In NATURE of September 9, 1939, p. 455, we emphasized that "It is the duty of the man of science to lay aside his just misgivings whether the greatest force of the human intellect should thus be harnessed to the forces of destruction. . . . The interests of pure science as an intellectual pursuit and discipline must remain in abeyance." The voice has proved strong and it did not cry in a wilderness. Science is being utilized in this war effort as never before. And now, we say, this voice must be even stronger. Our energies must be directed without remission to the cause of freedom. British and French men of science in collaboration, with the moral sympathy and active assistance of their American colleagues, must give their all, even at the expense of sacrificing or modifying their cultural pursuits. Thus alone can we hope for the overthrow of brute force and the speedy initiation of the period of reconstruction which shall enshrine the great prize of freedom.

CO-ORDINATION IN NATIONAL FOOD POLICY

THE new ministries established to deal with war-time problems must find it necessary to improvise policies and, since decisions are urgent, to adopt short-term arrangements for dealing with the manifold problems they are called upon to handle.

Food concerns every one of us. Food production and the trade in foods give employment to more people than any other form of industry or service. Hence it was only to be expected that the Ministry of Food should have become a target for a large volume of criticism.

As has already been pointed out in the leading article in NATURE of March 30, food policy has never been in peace-time the principal responsibility of any minister or of any Government department. Food production has been considered from the point of view of the farmer, imports of food as factors in commercial policy, food distribution as it related to the wholesale or retail trade. The Ministry of Health, largely preoccupied with the problems of local government, held a watching brief for the protection of the consumer from impure or adulterated food; but, although committees had been set up to consider nutritional requirements, there had been no attempt to co-ordinate ricultural, trade and health considerations into national food policy.

Since food supplies are one of the most vital ctors in national defence, the war-time Ministry Food, developed from the nucleus of the pre-war ood (Defence Plans) Department, had rapidly to olve such a co-ordination, and to do this simul- neously with the taking of decisions on every parate question concerning food.

The House of Commons, following a precedent the War of 1914–18, called into being a Select ommittee of the House to consider National xpenditure. This Committee consists of thirty- vo members of the House drawn from all parties. s main task is to consider whether full value is eing obtained from Government expenditure, and hether proper regard is being paid to economy. uch tasks inevitably involve the consideration of olicy. The fourth report of the Select Committee eals with the work of the Ministry of Food*. he functions of the Ministry are described, and ne report then deals with considerable frankness ith a number of matters of the greatest interest o national welfare and to the efficiency of our war ffort. Ministers of the previous Government have tated that Government policy was to subsidize ood in order to prevent an undue rise of prices. he Select Committee is clearly critical, not of his objective, but as to whether the subsidies hich are actually being given should be mainly egarded as contributions from the State to keep own food prices, since their main effect appears to e to increase the assistance given to United Kingdom farmers. The report contains paragraphs dealing with milk, bacon, meat and wheat, from hich it appears that the Committee tended to egard the sums, aggregating over £40,000,000, eing found by the Government for these foods as eing principally beneficial to agriculture.

The Committee asks whether reductions are ot possible "in the costs and profit margins llowed in all stages of manufacture, trading and ransport". The principal difficulty is the difference n efficiency between the large and the small con- ern. Striking contrasts in efficiency were brought o light by the National Expenditure Committee n the War of 1914–18, and the Costings Branch of he Ministry of Food has already accumulated onsiderable evidence of a similar character.

The tendency for decisions of great importance o be reached as a result of compromise between departments, or between the Ministry and a group of traders, is regarded as perhaps inevitable; but the Committee was clearly of opinion that the national interest might suffer. This consideration naturally led to the discussion of the utilization of trade directors of commodities often drawn from the trade with which the Ministry has to negotiate. While the Committee recognized the useful functions of trade directors, recommendations were made that all decisions on policy should be taken by the Minister on the advice of his Civil Servants.

Towards the end of the report, the Select Committee presented to the House a series of paragraphs referring to the need of forethought in dealing with the planning of food policy.

In these paragraphs the Committee suggested that "it must surely be right to be prepared for the possibility that shipping and other difficulties may necessitate wide modifications in existing diet and to devote the fullest scientific study to every possibility of providing the inhabitants in this country with a ration adequate in calories, etc., at a less cost in shipping and external currency than with the present normal form of diet".

The Committee went on to point out that this was not a matter for the Ministry of Food alone, that it involved the problem of nutrition and obviously also the question of what contribution home production can make. The Committee was obviously of opinion that, although this problem had no doubt been given some consideration, this had been of a "somewhat sporadic nature".

The Committee recognized that the scientific adviser to the Ministry of Food maintained contact with the scientific staff of other Ministries, but expressed doubts whether a single individual could possibly cope with the problems or determine how far scientific research was needed for their satisfactory solution. A Committee composed of scientific men and others was needed to enable full use to be made of scientific knowledge.

The new Government has lost little time in meeting this suggestion of the Select Committee. In the War of 1914–18 most useful services were rendered by a Scientific Committee established on the initiative of the Government under the auspices of the Royal Society. This precedent has now been followed and the Lord Privy Seal, as chairman of the Food Policy Committee of the Government, has announced the formation of an Advisory Committee to consider national food requirements and home food production (see NATURE of June 8, p. 887). The President of the Royal Society is to be chairman and the Society is further represented by four distinguished fellows, and by the Secretary to the Committee, three of whom are especially concerned with the physiological approach and two with crop production. There are two other well-known agricultural experts and an agricultural economist. Business has one representative in the vice-chairman, Sir Alan Anderson, while liaison with economics and finance is provided by the inclusion of Mr. Henry Clay, of the Bank of England, and now on Lord Stamp's Co-ordinating Committee.

---

* Fourth Report from the Select Committee on National Expendi- ure. Pp. 60. (London: H.M. Stationery Office, 1940.) 1s. net.

The Advisory Committee, consisting of a chairman, vice-chairman, secretary and eight members, is not an unwieldy body, and, provided the Departments supply it with the fullest information and assistance, it should be able to perform most useful functions.

Its reports will presumably be made to the Food Policy Committee of the Government itself, and its task is nothing less than the evolution of a food policy for the nation. There can be no doubts as to the importance of food in war, nor of the urgency of bringing about the fullest co-ordination between the nutritional needs of the country, food production and the many factors affecting import policy, that is, shipping, financial considerations and the exigencies of economic warfare. Many of the policies evolved will need to be continued during the first years of peace, and it is to be hoped that the pressing necessities which are at last leading to the formulation of a war-time food policy will not be considered as unimportant when peace has been firmly re-established.

The Advisory Committee might therefore regard its task as consisting of, first, urgent and immediate problems to ensure the maintenance of the physical vigour and morale of a nation fighting not only for its existence but also to save the world from the dominance of Nazism; and, secondly, to secure that, on a longer range basis, the newer knowledge of nutrition shall be allowed to bring its full influence to bear upon public health. This, as the Final Report of the League of Nations Committee on Nutrition shows, involves the closest relationship between health, agriculture and commercial policy.

From the point of view of the immediate task, it is greatly to be regretted that the Advisory Committee was not set up months ago. The agricultural season is now advanced, and, although in certain directions it is not too late for action affecting this season to be taken, yet far more could have been accomplished had the need for agricultural policy to be determined by the food requirements of the nation been recognized earlier.

A single example will suffice to illustrate this point. United Kingdom agriculture is mainly based upon animal husbandry, and this, in turn, has depended to a very great extent upon imported feeding stuffs. The British Isles has, however, a largely unexploited asset in its grass. The normal processes of haymaking and aftermath involve an enormous waste of valuable food for animals. There is extreme need for pasture improvement and for better conservation of the food values of young grass. The fact that so little has yet been done to secure the fuller utilization of this great asset is not due to any lack of knowledge of practical means for securing both objectives. Sir George Stapledon and others have for years been both preaching and demonstrating methods whereby the yields from pastures could be doubled. So far as conservation is concerned, cheap and practical methods of making first-class silage from young grass in pits or trenches are well known and have been fully demonstrated. Had vigorous action been taken before the summer flush of grass commenced, sufficient silage could have been conserved to have made a most important contribution to the maintenance of dairy herds during the coming winter, thus reducing the need for imported feeding stuffs or, alternatively, increasing the allowance for poultry or pigs. Given immediate and most vigorous action, a good deal of silage might yet be made, but the major opportunity has been lost for this season.

On this, as on other problems, the members of the Advisory Committee will themselves bring both expert and practical knowledge to the service of the country. More important still, they will, through their scientific associations, have access to the vast mass of information which is available on nutrition, public health, and the impact of biological science upon agriculture. The membership includes men of vision and decision, and it may confidently be anticipated that the Cabinet Food Policy Committee will receive sound advice without unnecessary delays. What may be more in question is whether early action will be taken to make effective use of the advice tendered. A great mass of tradition has to be overcome, vested interests may be in opposition; the Food Policy Committee of the Government will need to exercise considerable resolution if maximum benefits are to be derived from this belated but wholly desirable development.

THE GENUS LILIUM

A Supplement to Elwes' Monograph of the Genus Lilium

By A. Grove and A. D. Cotton. Seven parts. (London: Dulau and Co., Ltd., 1935–1940.) £19 13*s*. 9*d*.

DURING 1877–80 appeared a monumental work by H. J. Elwes entitled "A Monograph of the Genus Lilium". In this publication a series of magnificent plates represented all the lilies at that time in cultivation in Great Britain, the figures being drawn from actual living specimens. Elwes recognized that his work was incomplete, as many other species had still to be introduced into European cultivation. It was characteristic of his enthusiasm and energy that immediately on publication of his monograph he began the long and laborious task of collecting material for a supplement. This he pursued for many years, and although length of life was given to him in full measure, it was not sufficient for the completion of his aim. Associated with him in assembling this additional material was Mr. Arthur Grove, who among other pursuits has devoted a long life to the cultivation and study of lilies. The task has been almost too great for Mr. Grove, but he was fortunate in being able to call in as a colleague Mr. A. D. Cotton, keeper of the Herbarium at the Royal Botanic Gardens, Kew. These two authors have now carried to a conclusion the publication of a valuable supplement, which has been produced in the same form as the original monograph.

Botanical and horticultural publications reached a very high standard during the nineteenth century, and especially in the accuracy and artistic merit of the illustrations they contained. In the present century corresponding publications have not surpassed the products of nearly a hundred years ago, and many would say that they have lagged decidedly behind in their quality. Among these publications of the past the monograph of Elwes is one of the outstanding examples, and appreciation of this is shown by a market value which several times exceeds the original published price. The same is true of another publication of Elwes, entitled "The Trees of Great Britain and Ireland", which was issued in collaboration with the late Prof. Augustine Henry. One may say that the supplement now under review shows the same high quality both in text and in illustrations as was characteristic of the century that is past. As it forms a natural corollary to the monograph, I anticipate that it will receive the same appreciation and that its value will continue to be augmented.

There are some genera of plants which always keep the love and devotion of the horticulturist, and among these, of course, are the rose and the lily. Enthusiasm for these does not always remain at the same level, but during the last thirty years there has been a great revival of interest in the genus Lilium. This may have been only fortuitous, but I am inclined to think that the explorations of these years in China, especially those which brought E. H. Wilson his fame, are in some measure responsible for the increased attention now given to these beautiful plants. This view seems to me to be confirmed by the appearance among the species figured of a large number of Chinese species of Lilium, some of which have already made themselves familiar objects in our gardens while others may yet do so. Among these one cannot fail to mention *L. regale*, *L. Henryi*, *L. Sargentiæ*, *L. Davidi*, *L. Willmottiæ*, *L. Duchartrei*, *L. Wardii*, and that is not the complete tale. This interest in the garden cultivation of Lilium has extended quite naturally to publications on the genus, and amidst many recent and valuable books the older ones on the subject are sharing in this appreciation. This is the case not only in Great Britain; the same attention is also shown in the United States and in France. Among all the publications dealing with the genus, Elwes' monograph and the present supplement occupy pride of place. The two combined form a work of which any possessor may well be proud. If one may judge from similar examples in the past and with the knowledge of the real merit of the work, one may safely prophesy that their scientific value will not diminish and that they will continue to be indispensable for all those interested in the genus.

The supplement has been issued in seven parts, and the number of full-page plates is thirty, as compared with forty-eight in the monograph. The foreword by Dame Alice Godman gives an outline of the genesis of the publication and of the difficulties encountered in the search for completeness of the record. Much is due to her for her support and interest from the beginning and for assuming the entire financial responsibility for the publication itself. The plates have been prepared by Miss Lilian Snelling, whose artistic talent combined with accuracy is well known in other fields of botanical illustration. In beauty as well as in their botanical details they are in my opinion superior even to the fine figures in the original monograph. When we come to the text prepared by the long and painstaking efforts of Messrs. Grove and Cotton, there is no question but that the supplement compares much more than favourably with the text of the monograph. The authors have spared no pains to investigate all the literature dealing with their subject. This has involved not merely reference to botanical literature in order to elucidate the taxonomy, history, and often intricate nomenclature of the species concerned, but also to the horticultural periodicals, for many useful hints concerning cultivation are included in their comments. Much of this valuable information would naturally come from Mr. Grove, who has been for so long an enthusiastic and successful grower of many of the species. The illustrations have been prepared exclusively from living specimens, and there is no doubt that the study of the species in the living state has added greatly to the accuracy of the work. The authors have safeguarded their results by borrowing historical specimens and much herbarium material from many centres throughout the world ; these they interpret in the light of living specimens. Their final judgment has been based in great measure on each species in life.

The perusal of the text will not fail to convince any reader of the scrupulous care and intensive research given to the issue of this supplement. It is admirably done. Of course, in these matters there is never full completion. A few species, which have never been in cultivation in Europe and of which little or nothing is known except the mummified remains in herbaria, have had to be omitted. The aim set by Elwes has been adhered to, and the illustrations feature the plants as they appear in our gardens. At the risk of praising it once again, I affirm that this supplement takes its place with the classics of last century and is no ephemeral but a perpetual treasure.

W. WRIGHT SMITH.

THE INSTITUTION OF ELECTRICAL ENGINEERS

The History of the Institution of Electrical Engineers (1871–1931)

By Rollo Appleyard. Pp. 342 + 38 plates. (London: Institution of Electrical Engineers, 1939.) 18*s.* 6*d.*

IN the sixty-odd years of its existence, progress in the electrical industry has been so extraordinarily rapid and the applications of electricity in the service of man so numerous and widespread that the passing of time may serve to dim or obscure the labours of those who have "directed and safeguarded electrical progress". That this may not be so, the Council of the Institution of Electrical Engineers very wisely decided on the preparation of a history of the Institution, and were fortunate in entrusting the work to Commander Appleyard.

Apart from due cognizance being taken of earlier electrical knowledge and the necessity to refer to post advances, it was decided to confine the history mainly to the sixty years from 1871, when the Society of Telegraph Engineers was founded, to 1931—a fitting limit to such a period of achievement, since it marked the centenary of one of the most fundamental and important of discoveries, namely, Michael Faraday's discovery of "the evolution of electricity from magnetism".

It is perhaps not unnatural that the energy and discoveries of many of the early pioneers of electrical science should be directed to the solution of what was then one of the most urgent problems of man—rapid and easy communication. In the period immediately prior to the formation of the Society of Telegraph Engineers, the importance of electrical telegraphy had irresistibly become recognized. By 1871 the nominal capital of telegraph companies registered in England had reached approximately £40 million, and the "need for a corporate organization to collect, to coordinate and to preserve the results of electrical investigations" had become apparent and found expression in the meeting held on May 17, 1871, at No. 2, Westminster Chambers, Victoria Street, S.W., the minute book of which contains the following eight names : W. Whitehouse ; Captain P. H. Colomb, R.N. ; Major R. H. Stotherd, R.E. ; Louis Loeffler ; Captain C. E. Webber, R.E. ; Captain E. D. Malcolm, R.E. ; Robert Sabine ; and Major Frank Bolton.

Rapidity of progress and extension of the spheres of activity and thought, arising in no small measure from developments such as the Gramme generator and the Jablochkoff lamp, brought about, within the short space of nine years, a broadening of the title to "The Society of Telegraph Engineers and of Electricians", which was later modified to "The Society of Telegraph Engineers and Electricians", under which title it became incorporated in 1883. Improvements in machines associated with such names as Siemens, Edison, Brush, Mordey, Hopkinson and Crompton, and the epoch-making discoveries of Swan and Edison in regard to lamps, provided stimulus for the plea for a society of "sound electricians and engineers only", having for its task the shaping of the practice of electrical engineering into "something like an art, having some definite rules and principles". The title was thus altered in 1888 to "The Institution of Electrical Engineers", under which, in 1921, was granted a Royal Charter of Incorporation. Meanwhile, communication had witnessed the introduction of telephony with the development of the telephone by Bell in 1875 and the microphone in 1878 by Hughes, whilst electrical measurement had advanced by the work of Ayrton, Perry and Thompson, to name only a few.

The period from 1888 was one of progress marked by the development of electrical distribution, transmission and the use of electrical energy spurred by improvements in dynamos, A.C. machines and transformers, at the hands of Hopkinson, Crompton, Mordey, Ferranti and others, until by the close of the century electric power had truly become a handmaid of industry. The application of electrical knowledge was finding an ever-widening field. Electric traction had already been introduced, and a paper by Lodge in 1898 on "Improvements in Magnetic Space Telegraphy" and contributions by Evershed, Dolbear, Willoughby-Smith, Marconi and Tesla inaugurated wireless telegraphy. Contemporary development of the steam turbine by Parsons afforded impetus to bulk generation of electric power, and extensive development of the industrial use of power during the War of 1914–18, followed by more encouraging legislation, brought into being its widespread distribution as afforded by our national 'grid' system. Development of the thermionic valve by J. A. Fleming and the addition to it of a third electrode by de Forest played an all-important part in the transition from wireless telegraphy of 1898 to wireless telephony or broadcasting, which came into service in 1922, soon to be followed by the 'phonofilms' or 'talking pictures' and 'television' of modern times.

This pattern of the development of electrical science and engineering, which has been carefully woven by the author from the work of the Institution and "those who gave it lustre", is coloured throughout by his apt interpretation of vital influences and their magnitudes, by his appreciation of the trials and difficulties inseparable from such progress, and by his skilful presentation of excerpts from discussions and proceedings to illustrate the trend of thought and enlightenment as each new contribution was made. Throughout the pages of the history, names and personalities stand forth in their proper perspective, and the historian brings to light many human characteristics which serve to make very real the personalities he portrays. Just prominence is also given to such important factors in the history of the Institution as its close and beneficial association with the Services, its acknowledgment of duty to the public as exemplified by the issue of rules and regulations governing the installation of equipment and by the encouragement of public interest in matters electrical, its early and sustained assistance to the establishment of a working system of electrical units and to the work of standardization, and its unremitting efforts and encouragement on behalf of the education and training of personnel.

That the preparation of this narrative was no mean task is amply demonstrated throughout the book. The author and all those who assisted in the historical researches are to be congratulated on the result of their labour, which occupied a period of three years, for in the fulfilment of the task there is presented a record and appreciation of those who have had the furtherance of the industry and the well-being of their fellowmen at heart; it will serve as a worthy source of inspiration for those who follow.

The volume, which contains a wealth of fine illustrations, is beautifully produced.

A. P. M. FLEMING.

GRAHAM WALLAS: A SCIENTIFIC HUMANIST

Men and Ideas

Essays. By Graham Wallas. Pp. 221. (London: George Allen and Unwin, Ltd., 1940.) 8*s*. 6*d*. net.

THOUGH the interests of the late Graham Wallas were essentially humanistic, there are more reasons than one why the recently published volume of his essays should receive attention in a journal which, while mainly devoted to the physical and biological sciences, takes cognizance of other work which is informed by the scientific spirit. Such work was that of Graham Wallas, who did great service in helping to make social science worthy of its name. He relates how, at the beginning of his maturer studies, he undertook a voyage of exploration among the papers of Francis Place, and how he came out of his years of research a different man. Research was thereafter the keynote of his intellectual life.

Shrewsbury and Oxford had done much for his general equipment, but the real work of Graham Wallas's life was bound up with London, its school system, and its University. Jeremy Bentham, the spiritual father of that University, had adopted as the aim of all his efforts "the application to the social sciences of the methods already invented for the natural sciences", as these methods presented themselves at the end of the eighteenth century. Graham Wallas adopted the same principle, but with the vital difference in practice that he was born within a year of the appearance of Darwin's "Origin of Species", and that as a youthful 'intellectual' he witnessed the lively controversies that ensued. No one who knew Graham Wallas as a man will be surprised to learn that as an undergraduate at Oxford he wrote to the professor of moral philosophy, defending the theory of evolution against an attack made by that functionary in the course of a lecture.

Graham Wallas was nearing his fortieth year when his "Life of Francis Place" appeared. In his fifties he produced his "Human Nature in Politics" and "The Great Society", and in his sixties "The Social Heritage" and "The Art of Thought". These important works bear the impress of his keen interest in the development, during that period, of a more helpful psychology than had hitherto been at the disposal of the cultivators of social science. They bear also the marks of the man of affairs, who had taken leading parts in the work of the old London School Board, the Education Committee of the London County Council, and the Senate of the University of London, who had undertaken lecturing tours in America, and had served on a Royal Commission on the Civil Service.

Besides his major contributions to the thought of his time, Graham Wallas wrote a number of articles and addresses, a selection of which, edited by his daughter, is given in "Men and Ideas". Some of these papers, such as those on Bentham, remain of substantial value in themselves. Others are of permanent interest as contemporary criticism of the movements to which they refer. His criticism of Froebelian pedagogy, for example, written forty years ago, showed the Froebelians that their master lived under the influence of pre-Darwinian science, and taught them to sift the chaff from the wheat in his teaching. It is, therefore, a paper to be reckoned with by the historian of English education, though the criticism does not apply at the present time. The same may be said of the paper on "Oxford and the Nation", written in 1908, and on "English and American Universities", written in 1914.

Graham Wallas devoted himself to research, and gratefully acknowledged his debt to those men of science who pursue their researches in laboratories, and whose example he followed. But he ventured also to give them a timely hint as to the futility of some work which passes as research and is rewarded with academic distinctions. "It may be essential", he said, "that a young astronomer should pass the years between twenty-one and twenty-three in mastering the mathematics of relativity or the quantum theory. Such work would not produce 'a distinct contribution to the knowledge of the subject', because that contribution has already been made by Einstein and Planck. But when Einstein dies, the collection of personal incidents in his life, or misprints in his editions, will be research." Wallas was capable, not only of a hearty laugh, but also of a shrewd thrust.

T. RAYMONT.

LOCATION OF INDUSTRY

The Location of Industry and the Depressed Areas
By Prof. S. R. Dennison. Pp. vii + 216. (London: Oxford University Press, 1939.) 10*s.* net.

MUCH is expected of the publications of the Economics Research Department of the University of Manchester, and if in some respects Prof. S. R. Dennison scarcely maintains that high standard, he has at least given us a work which no serious student of the Special Areas and the problems they present can afford to overlook. His admirable and careful analysis of the work of the Commissioners for the Special Areas, and appreciation of the results achieved and of the limitations inherent in either their work or policy, sets the problem in its true perspective in relation to unemployment and industrial development generally. While he appears to ignore the experimental character of the Special Areas Act on which stress was laid when the legislation was introduced, he recognizes that the Special Areas measures cannot continue indefinitely as they now operate, and that it will soon be necessary either to rescind them and leave the problem as it is or to extend them.

The second part of the book, in which in successive chapters Prof. Dennison discusses the problem of the Special Areas, the apparent drift of industry to the south and the nature and limitations of Government policy, is most valuable and constructive. He rightly points out that in any industrial system which is not entirely static, technical change coupled with occupational immobility must be a cause of some unemployment, more or less short-lived, but he is concerned at the effect of the immobility of unemployed workers coupled with the decreased mobility of labour generally, particularly as the greater freedom of the location of industry from supplies of raw materials involves the risk of periodic shifts at a greater frequency. He appears to consider that policy should therefore be directed towards increasing the mobility of labour, and he is of the opinion that the policy of transference has not been of a character appropriate to the needs of the Special Areas. Prof. Dennison insists that there are limits also to the possibilities of attracting industries to the Special Areas, particularly in the provision of trading estates, and considers that the Commissioners have never had a well-defined aim : attempts to attract industries and the reconditioning of areas to receive them are clearly inconsistent with a policy of transference.

In his analysis of the drift of the industrial population to the south, Prof. Dennison points out that the relative growth of the industrial population in London and the south-east was not due to the relative rate of expansion of the expanding industries, which expanded with almost equal or even greater rapidity elsewhere, but to the fact that in other areas a much greater proportion of the industrial population was employed in declining industries. The problem of the Special Areas emerges from a series of general changes in industrial structure, and the causes being deep-seated, any policy which deals merely with the symptoms of depression in the areas will be only palliative ; if the causes which have created the Depressed Areas are to be removed, the trends of locational change must be reversed. As the only alternative to a long process of attrition, Prof. Dennison somewhat reluctantly advocates a short-period policy of transference and of encouraging new industrial development in non-derelict Depressed Areas. Such a short-period policy may also throw further light on factors to be taken into account in deciding upon the merits of policy designed to deal with the long-period problems.

It is in the lack of constructive criticism and positive suggestion that Prof. Dennison's book falls short of the standard generally set in the publications of the Economics Research Department at Manchester where the work was carried out. This defect is the more conspicuous in the first part of the volume, in which the economic aspects of the location of industry are discussed in detail. Excellent as is much of the analysis, though sometimes one-sided, Prof. Dennison appears to stress the difficulties in the way of control to an extent which paralyses action. It is well, however, that the implications of control should be set forth with such lucidity, and that in appraising the recommendations of the Majority or Minority Reports of the Royal Commission we should keep in mind the difficulty of defining the areas within which control is to be exercised ; the necessity of basing a policy of control on fairly definite criteria ; the major problem of deciding between diversity and specialization of industries ; or the relation between control and long-term planning and their application not to industry in the abstract but to individual firms. We may equally be grateful for the warning against a too facile assumption that policy will necessarily be distinguished by thought for larger issues and long-period aims, undisturbed by irrational or vested interests.

Prof. Dennison's obvious dislike of control, though he clearly distrusts *laissez-faire*, may possibly be attributed in part to the fact that, by limiting himself to the economic side, he leaves out of account those other large aspects such as town and country planning and regional development with which location of industry is interlocked, and in which such factors as strategic considerations, the preservation of amenities and the like are making action imperative if irreparable damage is not to be done. With miscellaneous exceptions, expert opinion is moving solidly in favour of control of the location of industry, differing only in regard to the means by which control is to be exercised and its extent. So, too, while the report of the Royal Commission and the P.E.P. Report stress the need for the collection and co-ordination of information on the location of industry and on natural resources, Prof. Dennison makes the somewhat naïve suggestion that information already available affords adequate guidance for the location of industry in general.

Here and elsewhere, Prof. Dennison is open to criticism on the grounds of a disappointingly narrow approach. Nevertheless, his discussion of theories of industrial location, particularly of Weber and his school, and analysis of the various factors in location such as transport, labour, taxation, and relation to markets, form an admirable background to the more important part of the book. He makes free use of evidence presented before the Royal Commission, and however disappointing the absence of more positive conclusions may be, the book is one which makes a contribution to the accurate knowledge and diagnosis which Prof. Dennison rightly insists must form the basis of any successful policy. R. BRIGHTMAN.

THE EIGHTH AMERICAN SCIENTIFIC CONGRESS

BY DR. AUSTIN H. CLARK

THE Eighth American Scientific Congress was held in Washington, D.C., during May 10–18, 1940. This Congress was convened by the Government of the United States with two purposes in view. The first was to advance scientific thought and achievement by enabling the scientific men and women of the twenty-one American Republics to meet each other, to exchange ideas, and to form lasting friendships. The second was to assist in the celebration of the fiftieth anniversary of the Pan American Union.

Though primarily scientific, the Congress aimed at integrating science in the Americas with the social and political life of the people, for science can no longer be considered as separate and distinct from other forms of human activity. In our modern civilization science in one form or another enters into every element of our social structure. This is particularly true in the Americas, where the origin and development of science have been democratic to an extent known nowhere else. In the Americas science knows no social classes. All groups have contributed to its advancement. There it has arisen from the people as a whole; it has been, and is being, supported by the people as a whole; and its broad aim is the betterment of the condition of the people as a whole.

Man as he used to be, as he is to-day, and as he is to be in the future; his social organization, welfare, and activities of every kind, and especially man in his relation to America and other Americans —this was the broad subject that occupied the attention of the Eighth American Scientific Congress.

This attitude must not be mistaken for one of isolationism. For the American Republics are all keenly alive to their close affinities, individually and collectively, with the nations of the Old World. This was emphasized at the formal opening of the Congress on the evening of May 10 in a stirring and memorable address by President Franklin D. Roosevelt in which he said:

> "All of the men and women of this Pan American Scientific Congress have come here to-night with heavy hearts. During the past few years we have seen event follow event, each and every one of them a shock to our hopes for the peaceful development of modern civilization. This very day three more independent nations have been cruelly invaded by force of arms.
>
> "In some human affairs the mind of man grows accustomed to unusual actions if they are oft repeated. That is not so in the world happenings of to-day—and I am proud that it is not so. I am glad that we are shocked and angered by the tragic news from Belgium and the Netherlands and Luxembourg.
>
> "The overwhelmingly greater part of the population of the world abhors conquest and war and bloodshed—prays that the hand of neighbour shall not be lifted against neighbour. The whole world has seen attack follow threat on so many occasions and in so many places during these later years. We have come, therefore, to the reluctant conclusion that a continuance of these processes of arms presents a definite challenge to the continuation of the type of civilization to which all of us in the three Americas have been accustomed."

In his address, President Roosevelt acknowledged with appreciation the great achievements of science in the extension and development of modern civilization. He said that the objectives toward which science is striving are closer and more peaceful relations between all nations through the spirit of co-operation and the interchange of knowledge. He deprecated the idea that science is responsible for the present "attacks on civilization which are in progress elsewhere", remarking that, "The great achievements of science and even of art can be used to destroy as well as to create; they are only instruments by which men try to do the things they most want to do."

The comprehensive scope of the Congress and the interdigitation of science, as commonly understood, with other forms of human activity are well brought out by the titles of the sections into which the proceedings were divided. These were: I. Anthropological Sciences (Herbert J. Spinden, chairman; Alfred V. Kidder, vice-chairman; Julian H. Steward, secretary). II. Biological Sciences (Edwin G. Conklin, chairman; Henry A. Gleason, vice-chairman; James A. G. Rehn, secretary). III. Geological Sciences (T. Wayland Vaughan, chairman; Wendell P. Woodring, secretary). IV. Agriculture and Conservation (Hugh H. Bennett, chairman; Ernest G. Holt, secretary; J. L. Colom, assistant secretary). V. Public Health and Medicine (Thomas Parran, chairman; Hugh S. Cumming, honorary chairman; Lewis H. Weed, vice-chairman; A. M. Stimson, secretary; A. A. Moll, assistant secretary). VI. Physical and Chemical Sciences (Lyman J. Briggs, chairman; Eugene C. Crittenden, secretary). VII. Statistics (Stuart A. Rice, chairman; Raymond Pearl, vice-chairman; Holbert L. Dunn, secretary; Elizabeth Phelps, executive assistant). VIII. History and Geography (C. H. Haring, chairman ; Preston James, vice-chairman ; Robert C. Smith, secretary ; Frank Vane, assistant secretary). IX. International Law, Public Law and Jurisprudence (James Brown Scott, chairman ; Herbert F. Goodrich, vice-chairman ; George A. Finch, secretary ; William Sanders, assistant secretary). X. Economics and Sociology (Harold G. Moulton, chairman ; Benjamin Colby, secretary). XI. Education (Nicholas Murray Butler, chairman ; I. L. Kandel, vice-chairman ; Richard Pattee, secretary ; Harold Benjamin and George I. Sánchez, rapporteurs).

Of most immediate interest to everyone are the sciences grouped under public health and medicine. These in recent years have attracted much attention throughout the Americas. In this section 119 papers were presented. Most of them were of broad general interest from the point of view of public health, though some gave details of the latest work on important and widespread ailments, or on obscure or little-known tropical diseases.

The accumulation of adequate statistical information regarding the population is recognized throughout the Americas as a matter of vital importance. In the section on statistics there were 71 papers, covering nearly all phases of the subject. These were read by statistical experts from all the twenty-one American Republics. An examination of these contributions shows how closely the conditions among the people are now being checked throughout the western hemisphere.

There were many papers on sociology and economics, these subjects being treated both from the point of view of national units and from the point of view of a closer unification of the American Republics.

A closer unification of the American Republics envisions a greater uniformity in legal systems and in legal procedure than exists at present. There were 78 papers dealing with various aspects of international law, public law and jurisprudence. Many eminent jurists took part in the discussion, including the Ministers to the United States from El Salvador and Honduras, the Mexican Under-Secretary for Foreign Affairs, and three members of the faculty of law in the University of San Marcos at Lima, Peru, the oldest university in the Americas, founded in 1551.

There were 61 contributions in the section on education, and 64 in the section on history and geography.

Among the 42 papers in the section of agriculture and conservation, there were several of more than usual interest. Among these were the opening address by the Hon. Henry A. Wallace, Secretary of Agriculture, on "The Vital Role of Agriculture in Inter-American Relations", and another by the Hon. Gifford Pinchot, former Governor of Pennsylvania, on "Conservation as the Foundation of Permanent Peace". The papers as a whole covered a wide range of subjects. Soil erosion, the conservation of agricultural and forest resources, improved agricultural practices, and range problems in both South and North America received special attention.

In the section on geological sciences there were 57 papers dealing with all phases of the subject, though especially with the mineral resources.

The programme of the section of physical and chemical sciences included 62 papers, of which the most outstanding was a contribution by Prof. Albert Einstein, of the Institute for Advanced Study, Princeton University, entitled "Considerations concerning the Fundaments of Theoretical Physics" [see p. 920 of this issue].

There were 79 contributions in the section of biological sciences. Many of these were on various aspects of the extraordinarily rich fauna and flora of tropical America, though there were also many on genetics, evolution, distribution, and other topics.

The scientific programme was supplemented by an elaborate social programme which included, in addition to receptions, teas, garden-parties, and other entertainments, a visit to the famous Luray caverns of Virginia, and an inspection of the restoration of Colonial Williamsburg, Virginia, over which the "Grand Union", the predecessor of the present Union Jack, still flies.

On May 20 the delegates to the Congress were the guests of the American Philosophical Society at Philadelphia, the oldest scientific society in the United States, founded by Benjamin Franklin, and May 21 was set apart as Eighth American Scientific Congress Day at the New York World's Fair, the delegates from the Latin American Republics being the guests of the Fair throughout the day.

In the preparation and carrying out of this extensive social and scientific programme many individuals participated. Mr. Cordell Hull, Secretary of State, was honorary chairman of the Advisory Committee, of which the other cabinet officers were honorary vice-chairmen. On the organizing and advisory committees were practically all the outstanding men of science in the United States.

Those chiefly responsible for the success of the Congress were the Hon. Sumner Welles, Under-Secretary of State, president of the Congress and chairman of the Organizing Committee ; Dr. Warren Kelchner, chief of the Division of International Conferences, Department of State, executive vice-president of the Congress and vice-chairman of the Organizing Committee ; Dr. Alexander Wetmore, assistant secretary of the Smithsonian Institution, secretary general of the Congress and secretary of the Organizing Committee; and Dr. Frank B. Jewett, president of the National Academy of Sciences, chairman of the Advisory Committee.

The Congress was adjourned with the same note of uneasiness and apprehension with which it had been opened by President Roosevelt. In his farewell address, Mr. Sumner Welles said:

> "You scientists have been free to seek the truth for the sake of that truth. You have been free to use your great powers without hindrance. You have been free to publish the results of your quiet study in your laboratories, or your often hazardous observations, sometimes at the far ends of the earth, without fear that because these results might differ from accepted concepts, you, and even your families, would be subjected to the control and the oppression of the State.
>
> "The suppression in some parts of the world to-day of the right of free inquiry, and the endeavour to control the thoughts of men, is therefore of intimate concern, not only to all scientists but likewise to all persons who believe that science has within its grasp the capacity to remedy in great part the ills of our present civilization. We cannot but speculate whether, in those parts of the world where free inquiry is no longer possible, there will not be, at least in so far as the things of the mind and the spirit are concerned, a return to the Dark Ages. What hope is there for future generations in countries where the State by fiat has declared that all persons must believe glaring distortions of the truth; where evil is declared to be good; where falsehood is paraded as the truth; and where aggression, pure and simple, is represented as self-defence? . . .
>
> "I believe—as firmly as I believe that the sun will rise once more to-morrow—that the present menace to civilization will pass, and that the day will come when the now destructive forces of evil which men themselves have created will be vanquished. I believe that mankind will again be afforded opportunity to lay the foundations of a better world—a world in which freedom from fear will be established for all mankind and the right of every person to worship God, to think, to speak, to know the truth and to search for the truth will be made sure."

CONSIDERATIONS CONCERNING THE FUNDAMENTS OF THEORETICAL PHYSICS*

BY PROF. A. EINSTEIN, FOR.MEM.R.S.,
INSTITUTE OF ADVANCED STUDY, PRINCETON UNIVERSITY

WHAT we call physics comprises that group of natural sciences which base their concepts on measurements; and the concepts and propositions of which lend themselves to mathematical formulation. Its realm is accordingly defined as that part of the sum total of our knowledge which is capable of being expressed in mathematical terms. With the progress of science, the realm of physics has so expanded that it seems to be limited only by the limitations of the method itself. The larger part of physical research is devoted to the development of the various branches of physics, in each of which the object is the theoretical understanding of more or less restricted fields of experience, and in each of which the laws and concepts remain as closely as possible related to experience. It is this department of science with its ever-growing specialization, which has revolutionized practical life in the last centuries.

On the other hand, from the very beginning there has always been present the attempt to find a unifying theoretical basis for all these single sciences, consisting of a minimum of concepts and fundamental relationships, from which all the concepts and relationships of the single disciplines might be derived by logical process. This is what we mean by the search for a foundation of the whole of physics.

It is clear that the word foundation in this connexion does not mean something analogous in all respects to the foundations of a building. Logically considered, of course, the various single laws of physics rest upon this foundation. But whereas a building may be seriously damaged by a heavy storm or spring flood, and yet its foundations remain intact, in science the logical foundation is always in greater peril from new experiences or new knowledge than are the branch disciplines with their closer experimental contacts.

The first attempt to lay a uniform theoretical foundation in physics was the work of Newton. In his system everything is reduced to the following concepts:

(1) Mass points with invariable mass;
(2) action at a distance between any pair of mass points;
(3) law of motion for the mass point.

There was not, strictly speaking, any all-embracing foundation, because an explicit law was formulated only for the actions-at-a-distance of gravitation; while for other actions-at-a-distance nothing was established *a priori* except the law of equality of

---

* An address, slightly abridged, delivered at the Eighth American Scientific Congress at Washington on May 15.

actio and *reactio*. Moreover, Newton himself fully realized that time and space were essential elements as physically effective factors of his system, if only by implication.

This Newtonian basis proved eminently fruitful and was regarded as final up to the end of the nineteenth century. It not only gave results for the movements of the heavenly bodies down to the most minute details, but also furnished a theory of the mechanics of discrete and continuous masses, a simple explanation of the principle of the conservation of energy, and a complete and brilliant theory of heat. The explanation of the facts of electrodynamics within the Newtonian system was more forced; least convincing of all, from the very beginning, was the theory of light.

It is not surprising that Newton would not listen to a wave theory of light; for such a theory was most unsuited to his theoretical foundation. The assumption that space was filled with a medium consisting of material points that propagated light waves without exhibiting any other mechanical properties must have seemed to him quite artificial. The strongest empirical arguments for the wave nature of light, fixed speeds of propagation, interference, diffraction, polarization, were either unknown or else not known in any well-ordered synthesis. He was justified in sticking to his corpuscular theory of light. During the nineteenth century the dispute was settled in favour of the wave theory. Yet no serious doubt of the mechanical foundation of physics arose, in the first place because nobody knew where to find a foundation of another sort. Only slowly, under the irresistible pressure of facts, there developed a new foundation of field-physics.

From Newton's time on, the theory of action-at-a-distance was constantly found artificial. Efforts were not lacking to explain gravitation by a kinetic theory, that is, on the basis of collision forces of hypothetical mass particles. But the attempts were superficial and bore no fruit. The strange part played by space (or the inertial system) within the mechanical foundation was also clearly recognized, and criticized with especial clarity by Ernst Mach.

The great change was brought about by Faraday, Maxwell and Hertz—as a matter of fact half-unconsciously and against their will. All three of them, throughout their lives, considered themselves adherents of the mechanical theory. Hertz had found the simplest form for the equations of the electromagnetic field, and declared that any theory leading to these equations was Maxwellian theory. Yet towards the end of his short life he wrote a paper in which he presented as the foundation of physics a mechanical theory freed from the force-concept.

For us, who took in Faraday's ideas so to speak with our mother's milk, it is hard to appreciate their greatness and audacity. Faraday must have grasped with unerring instinct the artificial nature of all attempts to refer electromagnetic phenomena to actions-at-a-distance between electric particles reacting on each other. All these electric particles together seemed to create in the surrounding space spatial states, to-day called fields, which he conceived as states of mechanical stress in a space-filling medium, similar to the states of stress in an elastically distended body. For at that time this was the only way one could conceive of states that were apparently continuously distributed in space. The peculiar type of mechanical interpretation of these fields remained in the background —a sort of placation of the scientific conscience in view of the mechanical tradition of Faraday's time.

With the help of these new field concepts, Faraday succeeded in forming a qualitative concept of the whole complex of electromagnetic effects discovered by him and his predecessors. The precise formulation of the time-space laws of those fields was the work of Maxwell. Imagine his feelings when the differential equations he had formulated proved to him that electromagnetic fields spread in the form of polarized waves and with the speed of light! At that thrilling moment he surely never guessed that the nature of light, apparently so completely solved, would continue to baffle succeeding generations. Meantime, it took physicists some decades to grasp the full significance of Maxwell's discovery, so bold was the leap that his genius forced upon the conceptions of his fellow-workers. Only after Hertz had demonstrated experimentally the existence of Maxwell's electromagnetic waves did resistance to the new theory break down.

But if the electromagnetic field could exist as a wave independent of the material source, then the electrostatic interaction could no longer be explained as action-at-a-distance; and what was true for electrical action could not be denied for gravitation. Everywhere Newton's actions-at-a-distance gave way to fields spreading with finite velocity.

Of Newton's foundation there now remained only the material mass points subject to the law of motion. But J. J. Thomson pointed out that an electrically charged body in motion must, according to Maxwell's theory, possess a magnetic field the energy of which acted precisely as does an increase of kinetic energy to the body. If, then, a part of kinetic energy consists of field energy, might that not then be true of the whole of the kinetic energy? Perhaps the basic property of matter, its inertia, could be explained within the field theory? The question led to the problem of an interpretation of matter in terms of field theory, the solution of which would furnish an explanation of the atomic structure of matter. It was soon realized that Maxwell's theory could not accomplish such a programme. Since then many men of science have zealously sought to complete the field theory by some generalization that should comprise a theory of matter; but so far such efforts have not been crowned with success.

For several decades most physicists clung to the conviction that a mechanical substructure would be found for Maxwell's theory. But the unsatisfactory results of their efforts led to gradual acceptance of the new field concepts as irreducible fundamentals—in other words, physicists resigned themselves to giving up the idea of a mechanical foundation.

Thus physicists held to a field-theory programme. But it could not be called a foundation, since nobody could tell whether a consistent field theory could ever explain on one hand gravitation, on the other hand the elementary components of matter. In this state of affairs it was necessary to think of material particles as mass points subject to Newton's laws of motion. This was the procedure of Lorentz in creating his electron theory and the theory of the electromagnetic phenomena of moving bodies.

Such was the point at which fundamental conceptions had arrived at the turn of the century. Immense progress was made in the theoretical penetration and understanding of whole groups of new phenomena; but the establishment of a unified foundation for physics seemed remote indeed; and this state of things has even been aggravated by subsequent developments.

The development during the present century is characterized by two theoretical systems essentially independent of each other: the theory of relativity and the quantum theory. The two systems do not directly contradict each other; but they seem little adapted to fusion into one unified theory.

The theory of relativity arose out of efforts to improve, with reference to logical economy, the foundation of physics as it existed at the turn of the century. The so-called special or restricted relativity theory is based on the fact that Maxwell's equations (and thus the law of propagation of light in empty space) are converted into equations of the same form, when they undergo Lorentz transformation. This formal property of the Maxwell equations is supplemented by our fairly secure empirical knowledge that the laws of physics are the same with respect to all inertial systems. This leads to the result that the Lorentz transformation—applied to space and time co-ordinates—must govern the transition from one inertial system to any other. The content of the restricted relativity theory can accordingly be summarized in one sentence: all natural laws must be so conditioned that they are co-variant with respect to Lorentz transformations. From this it follows that the simultaneity of two distant events is not an invariant concept and that the dimensions of rigid bodies and the speed of clocks depend upon their state of motion.

A further consequence was a modification of Newton's law of motion in cases where the speed of a given body was not small compared with the speed of light. There followed also the principle of the equivalence of mass and energy, with the laws of conservation of mass and energy becoming one and the same. Once it was shown that simultaneity was relative and depended on the frame of reference, every possibility of retaining actions-at-a-distance within the foundation of physics disappeared, since that concept presupposed the absolute character of simultaneity (it must be possible to state the location of the two interacting mass points "at the same time").

The general theory of relativity owes its origin to the attempt to explain a fact known since Galileo's and Newton's time but hitherto eluding all theoretical interpretation: the inertia and the weight of a body, in themselves two entirely distinct things, are measured by one and the same constant, the mass. From this correspondence follows that it is impossible to discover by experiment whether a given system of co-ordinates is accelerated, or whether its motion is straight and uniform, and the observed effects are due to a gravitational field (this is the equivalence principle of the general relativity theory). It shatters the concepts of the inertial system, as soon as gravitation enters in. It may be remarked here that the inertial system is a weak point of the Galilean-Newtonian mechanics. For there is presupposed a mysterious property of physical space, conditioning the kind of co-ordination systems for which the law of inertia and the Newtonian law of motion hold good.

These difficulties can be avoided by the following postulate: natural laws are to be formulated in such a way that their form is identical for co-ordinate systems of any kind of states of motion. To accomplish this is the task of the general theory of relativity. On the other hand, we deduce from the restricted theory the existence of a Riemannian metric within the time-space continuum, which, according to the equivalence principle, describes both the gravitational field and the metric properties of space. Assuming that the field equations of gravitation are of the second differential order, the field law is clearly determined.

Aside from this result, the theory frees field physics from the disability it suffered from, in common with the Newtonian mechanics, of ascribing to space those independent physical properties which heretofore had been concealed by the use of an inertial system. But it cannot be claimed that those parts of the general relativity theory which can to-day be regarded as final have furnished physics with a complete and satisfactory foundation. In the first place, the total field appears in it to be composed of two logically unconnected parts, the gravitational and the electromagnetic. In the second place, this theory, like the earlier field theories, has not yet supplied an explanation of the atomistic structure of matter. This failure has probably some connexion with the fact that so far it has contributed nothing to the understanding of quantum phenomena.

In 1900, in the course of a purely theoretical investigation, Max Planck made a remarkable discovery: the law of radiation of bodies as a function of temperature could not be derived solely from the laws of Maxwellian electrodynamics. To arrive at results consistent with the relevant experiments, radiation of a given frequency had to be treated as though it consisted of energy atoms of the individual energy $h\nu$, where h is Planck's universal constant. During the years following it was shown that light was everywhere produced and absorbed in such energy quanta. In particular, Niels Bohr was able largely to understand the structure of the atom, on the assumption that atoms can have only discrete energy values, and that the discontinuous transitions between them are connected with the emission or absorption of such an energy quantum. This threw some light on the fact that in their gaseous state elements and their compounds radiate and absorb only light of certain sharply defined frequencies. All this was quite inexplicable within the frame of the theories hitherto existing. It was clear that, at least in the field of atomistic phenomena, the character of everything that happens is determined by discrete states and by apparently discontinuous transitions between them, Planck's constant h having a decisive role.

The next step was taken by de Broglie. He asked himself how the discrete states could be understood by the aid of the current concepts, and hit on a parallel with stationary waves, as for example in the case of the fundamental frequencies of organ pipes and strings in acoustics. True, wave actions of the kind here required were unknown; but they could be constructed, and their mathematical laws formulated, employing Planck's constant h. De Broglie conceived an electron revolving about the atomic nucleus as being connected with such a hypothetical wave train, and made intelligible to some extent the discrete character of Bohr's 'permitted' paths by the stationary character of the corresponding waves.

Now in mechanics the motion of material points is determined by the forces or fields of force acting upon them. Hence it was to be expected that those fields of force would also influence de Broglie's wave fields in an analogous way. Erwin Schrödinger showed how this influence was to be taken into account, re-interpreting by an ingenious method certain formulations of classical mechanics. He even succeeded in expanding the wave mechanical theory to a point where, without the introduction of any additional hypotheses, it became applicable to any mechanical system consisting of an arbitrary number of mass points, that is to say, possessing an arbitrary number of degrees of freedom. This was possible because a mechanical system consisting of n mass points is mathematically equivalent, to a considerable degree, to one single mass point moving in a space of $3n$ dimensions.

On the basis of this theory there was obtained a surprisingly good representation of an immense variety of facts which otherwise appeared entirely incomprehensible. But on one point, curiously enough, there was failure: it proved impossible to associate with these Schrödinger waves definite motions of the mass points—and that, after all, had been the original purpose of the whole construction.

The difficulty appeared insurmountable, until it was overcome by Born in a way as simple as it was unexpected. The de Broglie – Schrödinger wave fields were not to be interpreted as a mathematical description of how an event actually takes place in time and space, though, of course, they have reference to such an event. Rather they are a mathematical description of what we can actually know about the system. They serve only to make statistical statements and predictions of the results of all measurements which we can carry out upon the system.

Let me illustrate these general features of quantum mechanics by means of a simple example: we shall consider a mass point kept inside a restricted region G by forces of finite strength. If the kinetic energy of the mass point is below a certain limit, then the mass point, according to classical mechanics, can never leave the region G. But according to quantum mechanics, the mass point, after a period not immediately predictable, is able to leave the region G, in an unpredictable direction, and escape into surrounding space. This case, according to Gamow, is a simplified model of radioactive disintegration.

The quantum theoretical treatment of this case is as follows: at the time t_0 we have a Schrödinger wave system entirely inside G. But from the time

t_0 onwards, the waves leave the interior of G in all directions, in such a way that the amplitude of the outgoing wave is small compared to the initial amplitude of the wave system inside G. The farther these outside waves spread, the more the amplitude of the waves inside G diminishes, and correspondingly the intensity of the later waves issuing from G. Only after infinite time has passed is the wave supply inside G exhausted, while the outside wave has spread over an ever-increasing space.

But what has this wave process to do with the first object of our interest, the particle originally enclosed in G? To answer this question, we must imagine some arrangement which will permit us to carry out measurements on the particle. For example, let us imagine somewhere in the surrounding space a screen so made that the particle sticks to it on coming into contact with it. Then from the intensity of the waves hitting the screen at some point, we draw conclusions as to the probability of the particle hitting the screen there at that time. As soon as the particle has hit any particular point of the screen, the whole wave field loses all its physical meaning; its only purpose was to make probability predictions as to the place and time of the particle hitting the screen (or, for example, its momentum at the time when it hits the screen).

All other cases are analogous. The aim of the theory is to determine the probability of the results of measurement upon a system at a given time. On the other hand, it makes no attempt to give a mathematical representation of what is actually present or goes on in space and time. On this point the quantum theory of to-day differs fundamentally from all previous theories of physics, mechanistic as well as field theories. Instead of a model description of actual space-time events, it gives the probability distributions for possible measurements as functions of time.

The new theoretical conception owes its origin not to any flight of fancy but to the compelling force of the facts of experience. All attempts to represent the particle and wave features displayed in the phenomena of light and matter, by direct recourse to a space-time model, have so far ended in failure; and Heisenberg has convincingly shown, from an empirical point of view, that any decision as to a rigorously deterministic structure of Nature is definitely ruled out, because of the atomistic structure of our experimental apparatus. Thus it is probably out of the question that any future knowledge can compel physics again to relinquish our present statistical theoretical foundation in favour of a deterministic one which would deal directly with physical reality. Logically, the problem seems to offer two possibilities, between which we are in principle given a choice. In the end, the choice will be made according to which kind of description yields the formulation of the simplest foundation, logically speaking. At the present, we are quite without any deterministic theory directly describing the events themselves and in consonance with the facts.

For the time being, we have to admit that we do not possess any general theoretical basis for physics which can be regarded as its logical foundation. The field theory, so far, has failed in the molecular sphere. It is agreed on all sides that the only principle which could serve as the basis of quantum theory would be one that constituted a translation of the field theory into the scheme of quantum statistics. Whether this will actually come about in a satisfactory manner, nobody can venture to say.

Some physicists, among them myself, cannot believe that we must abandon, actually and for ever, the idea of direct representation of physical reality in space and time; or that we must accept the view that events in Nature are analogous to a game of chance. It is open to every man to choose the direction of his striving; and also every man may draw comfort from Lessing's fine saying, that the search for truth is more precious than its possession.

OBITUARIES

Prof. Hugo Merton

THE Nazi régime has claimed as victim another scientific worker in the person of Prof. Hugo Merton, zoologist and traveller. In 1935 he was compelled to withdraw from his posts of deputy director of the Senckenberg Naturalist Society's Museum, assistant in the Zoological Institute of the University of Heidelberg and professor without chair of zoology, and in 1937, at the invitation of Prof. F. A. E. Crew, he went to the University of Edinburgh to work at the Institute of Animal Genetics. In the autumn of 1938 he set out for Heidelberg, but on reaching Germany was arrested and sent to the concentration camp at Dachau, and when he was released and returned to Edinburgh in the following year his health was broken. He died on March 23, 1940, sixty years of age.

Merton was educated at the Universities of Bonn, Berlin and Heidelberg, and specialized in the biological sciences. His many researches fall into groups, to each of which he made contributions of value: the histology of the sense-organs, nervous system and musculature of various molluscs; the anatomy and histology of the aberrant Temnocephala linking Turbellaria and Trematoda; studies on spermatozoa and experiments on ciliary movement and Protozoa, including his work on the geotaxis of Paramecium. In Edinburgh he concentrated upon physiological problems relating to sex.

But the most striking of all Merton's achievements was his expedition to the south-east Moluccas, undertaken on behalf of the Senckenbergischen Naturforschenden Gesellschaft. From October 1907 until August 1908 he explored the Aru and Kei Islands, bringing home vast zoological collections, the description of which by experts occupies two large volumes published at Frankfurt-am-Main in 1911 and 1913. The catholicity of his own interests is shown by his 200-page introductory account of the geography and ethnology of the islands.

Dr. Merton is survived by his widow, to whom the late Prof. Max Weber paid the compliment of dedicating one of his new species of fish from the Moluccas, on the ground that throughout she took an active part in the labours of her husband.

JAMES RITCHIE.

Prof. Pierre Marie

PROF. PIERRE MARIE, the celebrated French neurologist, whose death took place recently, was born on September 9, 1853, in Paris, where he received his medical education and qualified in 1883 with a thesis on the incomplete forms of Graves' disease, which afterwards became a classic. After serving as Charcot's chief assistant at La Salpêtrière he was elected physician in 1885 to the Bicêtre Infirmary, where he set up a rich collection of interesting records of cases, specimens and photographs of various diseases of the nervous system and attracted a large number of practitioners and students, many of whom have become distinguished neurologists. In 1907 he was elected professor of morbid anatomy in the Paris faculty of medicine in succession to Victor Cornil.

Prof. Marie made numerous valuable contributions to neurology. In addition to adding to our knowledge of well-recognized diseases such as rabies, disseminated sclerosis and epilepsy, he was the first to describe acromegaly (1886). In 1892 he brought out a book on diseases of the spinal cord which, like his articles on acromegaly, was published in English by the New Sydenham Society. In 1906 he caused a considerable sensation in the medical world by the publication of three articles on aphasia in the *Semaine Médicale*, in which he declared that the third left frontal convolution of the brain played no special part in the function of language, as had been maintained by Broca. During the War of 1914–18 he did valuable work in conjunction with his *interne*, Mme. Athanasio Benisty, on the symptoms and treatment of injuries of the nerves, which were published by her in the French "Horizon" series and in English form in the "Medical Military Manuals". In 1926 and 1928 he did good service to neurologists and others by publishing in two volumes, entitled "Travaux et Mémoires", the most important of his articles which had appeared in various periodicals and society reports.

J. D. ROLLESTON.

Prof. W. Blackadder

PROF. W. BLACKADDER, who died on May 14, graduated B.Sc. in engineering in the University of Edinburgh in 1897 and was awarded the Vans Dunlop Scholarship. After graduating he gained a wide experience in general engineering practice with the Caledonian Railway, Aberdeen Harbour Commissioners and the Clyde Navigation Trust. In 1907 he was appointed lecturer in civil engineering and applied mechanics in the Royal Technical College, Glasgow, under the late Prof. Longbottom, who at one time acted as assistant to the late Karl Pearson.

Prof. Blackadder was specially interested in structural theory and hydraulics and succeeded in developing this interest in students and staff alike. His teaching bore the hallmark of the master and was always abreast of modern developments. In 1924 he was appointed as first occupant of the Jackson chair of engineering in the University of Aberdeen and succeeded in building up a most efficient department. He was deeply interested in the welfare of his students and aimed at giving a sound theoretical training in engineering science in which the teaching of practical engineering formed little part except to illustrate to some small extent the application of that science in practice.

As a result of researches into the losses in turbine pumps and flow of water in looped pipes he was awarded the D.Sc. by his Alma Mater in 1923, while in 1932 he was awarded the Telford Premium by the Institution of Civil Engineers for his paper on "Direct Methods for Construction of Influence Lines for Continuous Girders".

WE regret to announce the following deaths:

Sir James Baillie, O.B.E., formerly vice-chancellor of the University of Leeds, on June 9, aged sixty-seven.

Sir Thomas Hudson Beare, regius professor of engineering in the University of Edinburgh, on June 10, aged eighty.

Mr. Oliver Gatty, research chemist, aged thirty-two, and Mr. A. S. Chessum, research engineer, aged twenty-seven, during an experiment in connexion with air raid precautions, on June 5.

Prof. A. E. H. Love, F.R.S., Sedleian professor of natural philosophy in the University of Oxford, on June 5.

Sir Jocelyn Thorpe, C.B.E., F.R.S., emeritus professor of organic chemistry in the University of London and in the Imperial College of Science and Technology, on June 10, aged sixty-seven.

NEWS AND VIEWS

Prof. T. Slater Price, O.B.E., F.R.S.

THE retirement has been announced at the end of the present academic year of Prof. T. Slater Price from the chair of chemistry at the Heriot-Watt Technical College, Edinburgh. Dr. Slater Price's early work was concerned with the oxidation of iodide by persulphates, with electro-analysis, and with the electrolytic method for the preparation of organic disulphides and diselinides. His interest in the oxyacids of sulphur continued, and he later provided some of the first evidence for the structure of Caro's acid. In 1903 he was appointed head of the Chemistry Department of the Birmingham Municipal Technical College, a position which he held with great success until 1920. There was, however, one interruption to this work at Birmingham; this was caused by his appointment, as Lieut.-Commander, R.N.V.R., to the Naval Experimental Station during 1916–19, where he carried out many valuable investigations on smoke screens, etc., for which he was afterwards given the O.B.E.(Mil.). Returning from this excursion, Dr. Slater Price met the chaos produced by a great influx of demobilized service men to technical classes. His Chemistry Department included pharmacy, so that the number of students to be accommodated was very large. However, order was soon established and the teaching work went on smoothly, though its demands prevented any rapid extension of the researches on complex cobaltammines upon which Slater Price had been engaged for several years.

Nor did Dr. Slater Price take up this work again, for in 1920 he was appointed director of the British Photographic Research Association, where he remained until 1930. The mechanism of light action on photographic materials was very little understood and formed a constant subject of research in his laboratory throughout this period, and by the end of 1930 work on the photoconductivity of silver halides had laid the foundations for much of the modern advance in the theory of the photographic image. The chemistry of the photographic emulsion also was studied, and much work was done on the influence of the chemical environment of the growing crystals of silver halide in a medium of gelatin and water. In spite, however, of the interest of industrial chemistry, the appeal of academic work was very strong, and in 1931 Dr. Slater Price returned to it once more in the post which he has held from that time, giving his energy in great part to the reorganization of his department, one section of which now includes equipment for micro-analysis. He has encouraged research by the members of his staff, one of whom is now studying the properties of chromium-ammines. Dr. Slater Price has also given much service on the councils of various scientific bodies, notably the Institute of Chemistry, the Chemical Society, and the Royal Photographic Society.

James Nevins Hyde (1840–1910)

DR. JAMES NEVINS HYDE, one of the most distinguished American dermatologists, was born at Norwich, Connecticut, on June 21, 1840, the son of a merchant. He received his medical education at the College of Physicians and Surgeons, New York, and qualified in 1869 at the University of Pennsylvania in Philadelphia. From that date until his death he practised in Chicago, where he was the principal pioneer in dermatology. His first appointment was that of lecturer in dermatology at the Rush Medical College from 1873 until 1876, when he was made professor of dermatology in the Northwestern University. Three years later he became professor of dermatology, genito-urinary and venereal diseases at Rush Medical College, and from 1902 until 1910 he held the chair of dermatology at the University of Chicago. He was also attending dermatologist to several hospitals in Chicago. His literary output was considerable. In addition to his principal work, "A Practical Treatise on Diseases of the Skin", which first appeared in 1883 and ran through eight editions, he contributed more than a hundred articles to dermatological literature. Hyde enjoyed an international reputation as shown by his membership of the dermatological societies of France, Italy, Berlin and Vienna. He was twice president of the American Dermatological Association and was secretary for America at the Fifth International Dermatological Association held in Berlin in 1904. He died suddenly at the age of seventy on September 6, 1910.

Dr. Waldemar Kernig

DR. WALDEMAR KERNIG, an eminent Russian physician, who died in 1917, was born on June 16, 1840, at Dorpat, where he received his medical education. He qualified in 1864 with a thesis on the regulation of the temperature in man and immediately afterwards became physician to the Obuchow Hospital at St. Petersburg. Subsequent posts held by him were those of physician to a deaf and dumb school from 1873 until 1890 and lecturer in internal medicine in the medical courses for women in the Empress Marie's institutions. He contributed several articles to periodical medical literature on splenic abscesses, subfebrile conditions of considerable duration, subcutaneous injection of Fowler's solution, etc., but he is best known by his name having been attached to a sign indicating meningitis which he described in two articles (*Berlin klin. Woch.*, 21, 829; 1884; and *Z. klin. Med.*, 64, 19; 1907).

M. V. Lomonosov

A LECTURE on Lomonosov (1711–1765), the first Russian man of science, will be given by Prof. J. D. Bernal at the Ambassadors' Hotel, W.C.1, at 7.30 p.m. on June 28. This fisherman's son from Archangel, his curiosity aroused by the icebergs and aurora borealis of his native province, ran away to school in Moscow at the age of nineteen. He entered the German-staffed Academy of Sciences set up by Peter the Great, being the first Russian to do so, and the first to lecture in his native tongue instead of in Latin.

He propounded theories on the structure of matter, the kinetic theory of gases, and the mechanical theory of heat, a hundred years in advance of their general introduction ; he built a 'thunder-machine' to study electricity ; he wrote about the physical condition of the sun, the atmosphere of Venus, metallurgy, and gravity ; he was the first to point out the possibility of the passage now established as the Great Northern Sea Route ; he published the first Russian grammar and founded the University of Moscow. Because he was only one outstanding figure in an age of absolutism, much of his work perished with him, and his importance as a pioneer has only recently been recognized. Further information concerning the lecture can be obtained from the Secretary, S.C.R., 98 Gower Street, London, W.C.1.

The British Pharmaceutical Conference

THE seventy-sixth annual meeting of the British Pharmaceutical Conference was the briefest in its annals. It was held at the headquarters of the Pharmaceutical Society on the afternoon of June 11, and the proceedings were limited to the address of the chairman, Mr. H. Humphreys Jones. The theme of the address was the role of pharmacists in relation to the food problem. He said that physiology is an integral part of the curriculum of study of the pharmaceutical student. Items in the syllabus are the physiology of the alimentary tract, comprising a knowledge of the control of salivary, gastric, pancreatic and biliary secretion. The chemistry of certain specified food sustances and the properties of the digestive juices and bile are also subjects of the curriculum. The main reason for their inclusion is, he said, the acceptance of the fact that pharmacists must keep pace with medical progress, and a further reason is the necessity for the pharmacist to be alive to the general awakening regarding food values. He must know not only the pharmacopœia —in which standards are laid down for certain organo-therapeutical substances, such as insulin, pituitary and thyroid as well as sera and vaccines— but also the chemistry of meat, eggs and bread and the properties of the digestive juices.

Mr. Humphreys Jones argued that, while in the past the aim of pharmacy has been to provide drugs to cure diseases rather than to prevent them, a wider vista has been opened up which invites the application of the knowledge of food values with a view to the prevention of disease and the maintenance of a general high standard of health at all periods of life. It has long been recognized that rickets, scurvy and many other diseases are due to the absence of certain food constituents ; this emphasizes the desirability of the close study by students of this part of the curriculum. In this connexion he said, "The [Pharmaceutical] Society has already done good work in connexion with vitamins. But why regard vitamins as the only important ingredients in real food ?" Hitherto, he said, the pharmacist has depended almost exclusively upon his own initiative and ingenuity ; as a servant of the State, his main privilege is that he can sell and dispense scheduled poisons and dispense medicines under the National Health Insurance Act. In Mr. Jones's view, there ought to be an avenue through which the pharmacist's knowledge of nutrition would be similarly recognized ; if a person is compelled by the State to pass an examination in a subject of first-class importance, he should be provided with the opportunity of utilizing that knowledge in the public service. In short, the public should be taught to regard the pharmacist as a dietitian.

The Institution of Professional Civil Servants

THE twenty-first annual report of the Council of the Institution of Professional Civil Servants, presented to the annual general meeting on April 25, indicates that in spite of the pre-occupation of Government departments, and especially the defence departments, with more pressing issues than service conditions, the Council has been available to secure a considerable number of increases in salary and other improvements in the conditions of employment. The report gives a review of activities which shows that the Council has fully maintained its vigilance over the interests of members in the difficult conditions of war-time, despite the removal to temporary offices and the heavier responsibilities falling on the honorary officers since the usual method of control by Council and its committees came in abeyance, and that claims or representations have been preferred with a sense of proportion and balance highly creditable to the Institution.

Special attention is given in the report of the Institution to numerous problems arising out of the evacuation of civil servants, of whom to date about 20,000 have been transferred to provincial towns. Concessions have been secured in regard to visits to families, billeting payments, daily travelling expenses and the like, and the formation of committees of the staffs of evacuated departments in the reception towns is being attempted. Numerous details are included in the report of representations on matters affecting the staffs of Government scientific establishments.

Scientific Films in War-Time

THE London Scientific Film Society gave four shows last winter of scientific and documentary films and received encouraging support. A new form of programme was generally appreciated. Several films with a common subject or theme were shown together ; programmes on contrasting or complementary treatments of psychology, civics in Great Britain, and agriculture being presented. All films shown by the Society are approved by the Scientific Films Committee of the Association of Scientific Workers, 30 Bedford Row, London, W.C.1. This body was set up in 1937 to further the interests of the scientific documentary film, to encourage the making and to sponsor the exhibition of such films. The films are broadly of three kinds: interpretative films, which bring out the relations of science to society and which try to smooth out the difficulties arising from developments and changes in science and social life; educational films, aiming simply to instruct; and research films, serving as a scientific instrument in the hands of the research worker. The Scientific Films Committee grades films into classes in this way, and also appraises their scientific value. The Committee's lists can be obtained on application; universities, schools and scientific societies can use them to help in making up programmes of scientific films. The work of appraising films will go on through the summer. In addition, the Committee's advice is available to producers, and recommendations for new films are to be made; certain subjects, such as chemistry, are very inadequately covered. The Committee wants the opinions of teachers and heads of scientific departments on what is needed, and the special requirements of war-time will be borne in mind.

Radiotherapeutic Panel of Physicists

SINCE the gift of a large sum of money to the King Edward's Hospital Fund by Sir Otto Beit in 1928 for the purchase of radium for use in the treatment of cancer, the Fund has taken an ever-increasing practical interest in the work associated with this and other gifts especially reserved for radium. When the National Radium Commission came into being in 1929, working arrangements were soon made between it and the Fund whereby the latter body became responsible for seeing that the radium needs of the London area were satisfied. In the developments of the last few years, the Fund has been assisted by an expert Radium Committee, which is now presided over by Sir Cuthbert Wallace. Recently this Committee has been considering in what way radiological treatment could be improved, and the Fund has approved the formation of a panel of consultant physicists. The chief reason that has led to this step is the realization that radiotherapy should be, can be, and is at some centres carried out on a quantitative basis, and that for this purpose the services of a physicist are necessary. The panel is designed to serve the needs of the many hospitals in which radium and X-ray treatment is carried out, but at which the employment of a physicist is precluded by expense. The groups of physicists constituting this panel are as follow: Dr. H. T. Flint and colleagues, Physics Department, Westminster Hospital, S.W.1; Mr. L. G. Grimmett and colleagues, Physics Department, Radium Beam Therapy Research, Radium Institute, Ridinghouse Street, W.1; Prof. F. L. Hopwood and colleagues, Physics Department, St. Bartholomew's Hospital, E.C.1; Dr. W. V. Mayneord and colleagues, Physics Department, Royal Cancer Hospital, Fulham Road, S.W.3; Prof. S. Russ and colleagues, Physics Department, Middlesex Hospital, W.1.

African Studies in War-time Paris

WHILE the intellectual and scientific activities of Paris, like those of London, suffered dislocation at the outbreak of war, efforts have been and continue to be made to resume them in as full a measure as is compatible with the demands of war on the resources of the city. In a review of what has been accomplished so far, with special reference to the facilities for African studies, Prof. Henri Labouret (*Africa*, 13, 2; 1940) refers to the action of the Government in sanctioning the reopening of the École Nationale de la France d'Outremer (École Coloniale). As an adjunct, the public as well as the students have been readmitted to the facilities for reading and study in the libraries and exhibition galleries of the Musée de l'Homme (Trocadéro) and the Institut d'Ethnologie. The Institut Français d'Anthropologie, the Société des Africanistes and the Société d'Anthropologie have resumed work and are to continue their meetings.

In view of the need for the extension of the co-operation of French and British authorities in Africa to the field of scientific research—a need which should be self-evident—it is interesting to note that M. Labouret is able to record that the Institut Français d'Afrique Noir, although it has lost a number of its most prominent supporters, has survived the crisis. This body was founded in 1938 only, but is already recognized as an important centre of African research. It will continue to publish its substantial *Notes Africaines*, and has taken over the responsibility of issuing the *Bulletin du Comité d'Études Historiques et Scientifiques de l'Afrique Occidentale Française*, founded by Prof. M. Delafosse in 1915. It will appear, however, in a new and enlarged form.

Daytime Lighting of Blacked-out Factories

THE Industrial Health Research Board is at present investigating the effects of complete obscuration of daylight on health and output, and also the problem of securing the best artificial lighting during the hours of daylight. R. Maxted and J. Bertram, who have been associated with this work, have written an interesting account in the *Electrical Times* of June 6 of experiments in factory lighting, reproducing by artificial means the most desirable features of natural lighting. Normal modern practice, based on pre-War experience, dwells on the importance of adequate illumination levels and of limitation of glare. But war-time conditions have greatly accentuated defects which were tolerable under peace conditions of working. In addition, the blacking-out of windows and skylights has usually resulted in conditions such that the psychological effect is of a magnitude creating an entirely new factor. It is unavoidable that operatives are required to work longer hours. It is obviously vital to ensure that any sense of strain is not associated in their minds with factory conditions, which should clearly be designed to conserve both mental and physical reserves. No other factor is more potent psychologically than the lighting installation. Diagrams are given showing the objectionable tunnel effect produced when the natural skylights are blacked out. The absence of distracting dazzle and the avoidance of glare raise and maintain the output of the factories.

War-Time Museum Exhibitions

THE *Museums Journal* of May shows in what way many museums in Great Britain are endeavouring to stimulate interest by supplying information bearing upon warfare or upon the needs which it has created. In the former group is the special war-time exhibition at the National Maritime Museum, described by Sir Geoffrey Callender. Two contrasting sets of medals are shown, one German and one wrongly described as "English", for the only representative mentioned is "the General Service Medal conferred on *British* officers and men" during the Napoleonic wars. Lightship and lifeboat models, models showing the story of the development of the torpedo-boat, and of the evolution of anchors from their simple beginnings as heavy stones, are arranged with larger exhibits such as that illustrating the evolution of naval ordnance, to make a varied show which as a whole illustrates "the age-long character of our sea-experience and the continuity of our maritime prestige". The second type of exhibit has been created in several museums "to show how the various kinds of foods, essential to man's existence, may be provided by vegetables and grown on a small allotment or in a garden". Several illustrations indicate how, by models of garden plots and cropping plans, this good work may be pursued.

Investigation of Atmospheric Pollution

REPRESENTATIVES of local authorities and other bodies co-operating in the investigation of atmospheric pollution met in London on May 28. The Conference, in considering its annual report to the co-operating bodies, unanimously agreed that while contribution to the war effort is the first duty and desire of every organization, the need for vigilant attention to the purity of the atmosphere has by no means decreased since the outbreak of the War. The wasteful burning of fuel, and the detriment which pollution causes to the nation's health were stressed. The Conference therefore urged all local authorities to do whatever lies in their power to maintain the investigation. At the close of the meeting, Prof. W. H. Roberts, associate professor of public health chemistry in the University of Liverpool, was unanimously elected chairman of the Conference.

Electricity Applied to Metallurgy

IN the Menelaus Memorial Lecture delivered to the South Wales Institute of Engineers on March 19, Dr. A. P. M. Fleming chose as his subject "Electricity as applied to Metallurgy". A most important application arises in connexion with methods of testing. Dr. Fleming points out that electricity has proved an invaluable aid to the metallurgist when making fine measurements and researches, as well as for checking the quality of his materials. Using standardized specimens the composition and heat treatment of which are known, comparisons may be made of unknown specimens by magnetic testing. By suitable exploration of the magnetic behaviour of the specimen in an alternating magnetic field, it is possible to relate the phase and quadrature components of the voltage induced in a search coil, and by comparing these with the standardized specimen, definite inferences can be drawn as to the composition of the material without the necessity of destroying the specimen under test.

Magnetic methods have also been developed for fault detection, and have been of increasing importance due to the tendency to cut down material costs and weight, while still maintaining the safety factor, by more rigid inspection and care in production. The presence of a fault or change in magnetic composition can be detected by the distortion these cause in the magnetic field, the distortion being located either by a direction indicator like a magnetic needle or a moving search coil. Another and most valuable method is that developed largely by the Metropolitan-Vickers Electrical Co., Ltd., in which the specimen is magnetized and then subjected to examination under a coating of liquid containing very finely divided magnetic particles. When examining material in the shape of a bar for longitudinal cracks, a heavy current is passed down the bar while it is immersed in a bath of finely divided magnetic particles, suspended in a light oil. These particles form sharply defined lines which indicate the flaws. This method is of growing importance, and is probably the most effective means at present available of checking this form of weakness in metals.

Incorporated Municipal Electrical Association

THE activities of the Incorporated Municipal Electrical Association (I.M.E.A.) are described in the *Electrical Review* of May 10. The Association is taking steps to ensure that stocks of coal held by public utility undertakings in Great Britain shall be built up during the coming months to ensure that by September 30 the undertakings will have not less than ten winter weeks supply on hand. The Council has agreed that a scheme of insurance in respect to war damage to electricity undertakings should be prepared and has referred the matter to the Joint Committee of Electricity Supply Associations. The members of the Association have been recommended by the National Whitley Council to grant a temporary increase of salary to administrative, technical and clerical staffs. The Joint Committee of Electricity Supply Associations has approached the Minister of Home Security with a view to the relaxation of the restrictions upon the use of neon and other outdoor signs during hours of daylight.

The Finance Officer of the London and Home Counties J.E.A. (Mr. A. L. Burnell) recently prepared a memorandum on the transfer of hire-purchase agreements from one authority to another upon the removal of a consumer when he is unable immediately to complete payment. Difficulties are raised by the varying practice among undertakings in such matters as maximum periods, interest-rates, local limitations as to the type of apparatus and absence of hire purchase facilities in some areas, but all of these can be surmounted. Mr. Burnell suggests that all undertakings should be prepared to take over agreements on the original terms.

Cancer Research and Treatment in Australasia

THE Tenth Australian – New Zealand Cancer Conference, held at Wellington in February of last year, was concerned with cancer control, reports on particular forms of treatment (Koch and Baker) and radiological physics. The part being played by the physicist in the use of X-rays and radium is a rapidly growing one; this arises from the growth of quantitative methods in giving doses of radiation to patients. These methods not only allow the specification of the dose actually given, but also they aim at arranging for the optimum distribution of the radiation throughout the tissues. The report from the Commonwealth X-ray and Radium Laboratory shows a wide range of activity at this centre, with a most progressive outlook as to the function of the physicist in collaboration. It is good to learn that the Commonwealth Department of Health has made the services of the physicists-in-charge available to radiotherapeutic institutions for consultation on the various physical problems of X-ray and radium therapy, and advantage is being taken of such facilities, doubtless to the benefit of patients.

American Zeal for Education

SCHOOL and college summaries seem perpetual in the United States. "A Review of Educational Legislation: 1937 and 1938", by Mr. Ward Keesecker (Washington, D.C., 10 cents), has involved, we are told, a study of 1,500 enactments. The main tendencies exhibited are increased support from the State with more control and the establishment of minimum State-aid foundations. Pennsylvania in 1937 paid special attention to local schools, county boards of directors, the merging of schools poorly attended, and transportation routes. In Georgia all teachers now have to be classified according to their training and experience. In Nevada, amendment of the liquor-licence law increased the amount set aside for education. Tennessee added 4½ million dollars to school funds. Two States, Arkansas and Vermont, made teaching on the effects of alcohol compulsory from grades 3 to 8. Montana required all public schools to give instruction in music, art, and elementary agriculture. Several States increased the minimum salaries of teachers and their benefits on retirement, and Kentucky forbade city schools to discriminate against married women as teachers. It is clear that throughout the country great pains have been taken to see that education is better managed and financed.

Smithsonian Institution: Annual Report

THE report of the secretary of the Smithsonian Institution for the year ended June 30, 1939, which has been published, refers to the completion by the Astrophysical Observatory of the enormous task of recomputing the daily solar constant values from all its observing stations since 1923, apart from the final corrections and general discussion, which were expected to be concluded by October 1939. The Division of Radiation and Organisms gave much attention during the year to photosynthesis, factors influencing plant growth and the stimulative action of ultra-violet radiation. Experimental evidence was obtained indicating the formation during photosynthesis of a material which combines with or absorbs carbon dioxide and resembles chlorophyll in character. A quantitative method for the isolation of hormones from plants is being developed, and the effect of radiation on the growth of excised roots and leaves has been investigated.

Numerous scientific field investigations in anthropology have been conducted by the National Museum as well as archæological and ethnological expeditions by the Bureau of American Ethnology, including investigations of Folsom man at the Lindenmeier site in northern Colorado, studies in the northern province of the Navaho Indians, as well as in western South America. In addition to the report of the Executive Committee of the Board of Regents, appendixes include detailed reports of the work of the various divisions, including the National Gallery of Art, the Freer Gallery of Art, the National Collection of Fine Arts and the National Zoological Park, the last-named giving a detailed list of animals in the collection that had not previously been exhibited.

Awards of the Finney-Howell Research Foundation

THE Finney-Howell Research Foundation, Inc., of Baltimore, Maryland, announces that fellowships for research into the cause or causes and the treatment of cancer were renewed for the following: P. C. Aebersold, working at the Radiation Laboratory of the University of California at Berkeley; G. M. Badger, working at the Royal Cancer Hospital (Free) at London, England; Ll. W. Law, working at the Roscoe B. Jackson Memorial Laboratory at Bar Harbor, Maine; J. L. Melnick, working at Yale University School of Medicine at New Haven, Conn.; J. F. Menke, working at Stanford University Hospital, at San Francisco, California; J. L. Wood, working in the Division of Chemistry, Harvard University, at Cambridge, Mass.; P. C. Zamecnik, working at Copenhagen. New fellowships have been awarded as follows: J. C. Abels, to work at the Memorial Hospital for Cancer at New York City; M. A. Graubard, to work at Clark University, Worcester, Mass.; J. W. Howard, to work at Thorndike Memorial Laboratory, Boston City Hospital, Boston, Mass.; B. E. Kline, to work at the Department of Physiology, University of Wisconsin, Madison; Margaret N. Lewis, to work at Crocker Radiation Laboratory, University of California, Berkeley; A. Marshak, to work at the Radiation Laboratory, University of California, Berkeley; Dr. G. C. Gey was also awarded a grant of 2,000 dollars to carry on his work on cancer at the Johns Hopkins Medical School. The closing date for applications for awards during 1941 is January 1, 1941.

Bicentenary of the University of Pennsylvania

THE University of Pennsylvania, Philadelphia, celebrates this year the bicentenary of its foundation. During July and August, the laboratories, museums and libraries of the University, the Morris Arboretum and other places of interest will be open to visitors, and the principal celebrations will take place during the week September 15–21. The week will open with addresses by well-known authorities, which are intended not only to serve as tributes to the University of Pennsylvania but also to focus attention upon the contributions which higher education has made and can still make to the betterment of mankind. Among delegates announced from Great Britain are Sir Henry Dale, Sir Thomas Lewis, Sir William Beveridge, Prof. A. J. B. Wace, Sir Robert Robinson and Dr. C. S. Myers. Some forty symposia and conferences have been arranged to follow the general sessions. In connexion with the celebrations, a Bicentennial Fund has been inaugurated, and by the early part of April, more than four million dollars had already been subscribed, of which a half had been contributed by alumni of the University.

Announcements

SIR ARNOLD WILSON, K.C.I.E., C.S.I., C.M.G., M.P., distinguished for his administrative work in India and Persia, chairman of the Industrial Health Research Board during 1926–33, has been reported by the War Office as missing.

SIR FRANK E. SMITH, F.R.S., director of instrument production in the Ministry of Supply has, in addition, been appointed controller of telecommunications equipment with full authority, by the Minister of Aircraft Production.

MR. J. DAVIDSON PRATT has been appointed an additional deputy director-general for chemical research, experiment and development in the Ministry of Supply. Mr. Davidson Pratt has been since 1928 general manager of the Association of British Chemical Manufacturers, who have now agreed to second him for his present appointment.

THE joint committee of the Royal Society of Edinburgh, the Royal Physical Society and the Royal Scottish Geographical Society has awarded the Dr. W. S. Bruce Memorial Prize (1940) to Mr. Brian Roberts, Emmanuel College, Cambridge, for his valuable work in survey, ornithology and general biology in the north and south polar regions.

THE following appointments and promotions in the Colonial Service have recently been made: R. W. Rayner, plant pathologist, Kenya; C. B. Garnett, agricultural officer, Tanganyika Territory, to be marketing officer, Nyasaland; N. Humphrey, agricultural officer, to be senior agricultural officer, Kenya; E. B. Martyn, botanist and plant pathologist, British Guiana, to be plant pathologist, Jamaica; A. J. Wakefield, director of agriculture, Tanganyika Territory, to be inspector general of agriculture in the West Indies; R. H. Tyrwhitt-Drake, director of surveys, Zanzibar, to be director of surveys, Kenya; G. B. Simmins, senior veterinary research officer, to be chief veterinary officer, Palestine.

MR. NORMAN NEVILLS will head an expedition of nine on a trip down the Green and Colorado Rivers, leaving Green River, Wyoming, on June 20, and arriving at Boulder Dam about August 25. The group will travel in three specially designed boats and make botanical and geological observations and collections in the little-known Canyon country. Dr. Hugh C. Cutler, of Washington University, is in charge of botanical research, and Mr. Nevills of the geological work.

THE Goethe Medal for Art and Science has been awarded to Heinrich Ewald Hering, formerly professor of physiology in the University of Cologne.

BY a recent decree the State has authorized the creation in French universities of faculties of pharmacy and the consequent granting of doctorates in pharmacy. By this action universities will rank pharmacy with the other four faculties—arts, law, sciences and medicine. Prior to this decree aspirants to high qualifications in pharmacy were awarded either a "doctorat d'Université, Mention pharmacie" or a "diplôme supérieur de pharmacie".

THE Council of the Royal Aeronautical Society has accepted an offer from Mrs. G. Alston to found a prize in memory of her husband Peter Alston who was killed in a flying accident on February 16, 1939. The prize, an annual one of approximately £5 in value, will be awarded for work aiming at the improvement of the safety of aircraft and particularly at improvement in stability and control, and such award is open to a student and/or graduate of the Society.

THE New York Academy of Sciences announces three prizes offered by Mr. A. Cressy Morrison, to be known as the A. Cressy Morrison Prizes I, II and III, all of which will be awarded in December 1940. Prize I, of five hundred dollars, will be awarded for the best paper on solar and stellar energy. Prizes II and III will be awarded for the best papers on a scientific subject included within the field of the New York Academy of Sciences and its affiliated societies. The competition for Prize I is open to all. Prizes II and III are limited to members of the New York Academy of Sciences and affiliated societies, but non-members may become eligible by joining one of these organizations before the closing date. Further information can be obtained from the Secretary, New York Academy of Sciences, Central Park West at 79th Street, New York City.

WHEN dealing with Dr. Haddon's second expedition to the Torres Straits (NATURE, June 1, p. 849) reference was made to Haddon's visit to New Guinea "with Ray and Seligman"; Prof. Seligman informs us that this should read "with Ray, Wilkin and Seligman".

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 940.

The Electronic Charge

THE determination of e by a new oil drop method in which the electric field is horizontal[1] has been completed. The expression for e in terms of the quantities measured is similar to that which applies to H. A. Wilson's method and is

$$ne_1 = 9\sqrt{2}\ \eta^{3/2}\ (\rho-\sigma)^{-1/2}\ g^{-1/2}\ v_g^{\ 1/2}\ v_x\ X^{-1}. \quad (1)$$

The correction for the departure from Stokes's law is obtained from Millikan's relation

$$e_1^{2/3} = e^{2/3} + m/pa, \quad (2)$$

where $e_1^{2/3}$ is calculated from (1) and p cm. of mercury is the pressure and a is radius of the drop (cm.). The oil drops used are larger than those used by previous experimenters, and their velocity of fall being large, their motion was recorded photographically using exposures of 0·0005 sec. at intervals of 1/25 sec. The velocity of free fall, v_g cm./sec. and the velocity in the direction of the electric field v_x cm./sec., could be estimated with satisfactory accuracy. The electric field was obtained by means of a stabilized rectifier designed by Mr. T. P. Gill[2] and was measured by potentiometer methods in terms of Weston cells calibrated by the National Physical Laboratory.

Assuming $\eta_{23} = 1{,}830 \times 10^{-7}$ C.G.S. units, the value of e obtained is $(4{\cdot}8020 \pm 0\ 0013) \times 10^{-10}$ E.S.U. The probable error calculated by the theory of least squares is about one third of that obtained by Millikan, whose result becomes $e = (4{\cdot}7992 \pm 0{\cdot}0037) \times 10^{-10}$ E.S.U. when the above value of η_{23} is assumed. Millikan's 0·03784 and our value 0 03777 of m are in agreement within the smaller probable error. There are two other determinations of e by the drop method, namely, by Bäcklin and Flemberg[3], and by Ishida, Fukushina and Suetsuga[4]. Their results yield $4{\cdot}781 \times 10^{-10}$ and $4{\cdot}835 \times 10^{-10}$ E.S.U. for e respectively, when η_{23} is taken as $1{,}830 \times 10^{-7}$ C.G.S. units.

Careful determinations of e using the X-ray method have recently been made by several workers, and our reduction of their observations is given in Table 1

TABLE 1. X-RAY VALUE OF e.

Observer	$e \times 10^{10}$ E.S.U.
Soderman	4·8054
Bäcklin	4·8044
Bearden 1935	4·8029
1931	4·8049
Mean	4·8044 ± 0·0007

These results differ slightly from those given by the observers themselves, as we have used what we believe to be the most accurate values of antecedent data in the reduction of the results of the above observers.

It will be seen that the mean of the X-ray, $(4{\cdot}8044 \pm 0{\cdot}0007) \times 10^{-10}$ E.S.U., and of the oil drop determinations of Millikan and the authors, $(4{\cdot}8007 \pm 0{\cdot}002) \times 10^{-10}$ E.S.U., differ by $0{\cdot}0037 \times 10^{-10}$. The main uncertainty in the value of e as found by the oil drop method is in the value which is used for the viscosity of air. In the paper to be published describing the present determination, the errors in the measurement of η_{23} by the rotating cylinder and the capillary-tube method are discussed. The most precise results obtained by these methods are given in Table 2, and using the weights given, the mean is $\eta_{23} = (1{,}830{\cdot}06 \pm 2{\cdot}5) \times 10^{-7}$ C.G.S. units. In this table the values of the viscosity have been recalculated using Sutherland's expression,

$$\eta_\theta = \eta_{273}\{(273+c)/(\theta+c)\}\ .\ (\theta/273)^{3/2},$$

where $c = 117$, for the change in viscosity with temperature. This gives the change in viscosity per degree at 23° C. as $4{\cdot}83 \times 10^{-7}$ C.G.S. units and not $4{\cdot}93 \times 10^{-7}$ units as is generally assumed.

TABLE 2. VISCOSITY OF AIR.

Method	$\eta_{33} \times 10^7$	Weight
Rotating cylinder:		
Bearden	1833·8	4
Houston	1829·2	3
Kellström	1832·6	2
Harrington	1822·6	1
Gilchrist	1825·7	1
Capillary Tube:		
Rigden	1830·0	2
Bond	1834·6	1
Rapp	1822·7	1
Maxwell	1827·3	1

Weighted mean = $(1830{\cdot}06 \pm 2{\cdot}5) \times 10^{-7}$ C.G.S. units.

It will be noticed that the probable error of η_{23} calculated by external consistence contributes an error in e of 1 in 500 compared with an error of 1 in 3,000 in the remaining factors which enter into expression (1), an error larger than the difference between the oil drop and X-ray values of e. Thus the uncertainty in η_{33}, although a number of precision determinations of it has been made, contributes the major uncertainty to the oil drop determination.

We are attempting to determine the viscosity of air with, it is hoped, improved precision, using a method suggested by Fabry and Perot[5] in which there is a laminar flow of the air between optically flat disks.

It may be noted that using $e = 4{\cdot}802 \times 10^{-10}$, $h/e = 1{\cdot}3765 \times 10^{-17}$ (a mean of h/e determined by the X-ray method and by Wien's law) and

$c = 2{\cdot}99774 \times 10^{10}$, then $1/\alpha = hc/2\pi e^2 = 136{\cdot}76$. If Rydberg's constant (109,737·43) and e/m ($1{\cdot}7589 \times 10^7$) are substituted in the formula $1/\alpha = (c/4\pi R(e/m)e)^{1/3}$, it then becomes 137·03, which is nearly integral.

Mass Centre in Relativity

UNDER this title, in NATURE of April 13, p. 587, Prof. M. Born and K. Fuchs gave some relations between the total and a relative momentum vector of a system of two free particles. They only define the magnitude, not the direction of their relative momentum vector. I believe things become clearer by the following statement. Let V^a, W^a $(a = 0, 1, 2, 3)$ be $(1 + 3)$-dimensional velocity time-space vectors of the particles ($V^2 = W^2 = c^2$), and m_1, m_2 their scalar masses. Their individual energy-momentum vectors being $i_a = m_1 V_a$ and $j_a = m_2 W_a$, we may define the total energy-momentum vector by

$$I_a = i_a + j_a, \qquad (1, 1)$$

the relative energy-momentum vector by

$$S_a = (m_2 i_a - m_1 j_a)/(m_1 + m_2). \qquad (1, 2)$$

These definitions entail two identities

$$(m_1 + m_2)\,c^2 = \frac{I^2}{m_1 + m_2} + \frac{m_1 + m_2}{m_1 m_2}\,s^2, \qquad (2, 1)$$

$$0 = \frac{2m_1 m_2}{m_1 + m_2}\,(I.s) - (m_1 - m_2)s^2, \qquad (2, 2)$$

which are equivalent to equations (4), (5), (6) of Born and Fuchs.

The total energy-momentum has a time vector character, whereas the relative energy-momentum has a space vector character. The two individual rest masses, being constants of the motion, must be functions of the eight dynamical variables I_a and s_a:

$$c^2\,(m_1 + m_2)^2 = I^2 + 2s^2 + 2\sqrt{s^4 + (I.s)^2}, \qquad (3, 1)$$

$$c^2\,(m_1 - m_2)^2 = I^2 - 2\,\frac{s^2 I^2 - (I.s)^2}{s^2 + \sqrt{s^4 + (I.s)^2}} \qquad (3, 2)$$

As regards the centre of mass, which has completely been lost sight of in the communication referred to, I suggest that the proper thing to consider is a centre of inertia rather than a mass centre. The former must be defined with the aid of the bi-vectors of energy and momentum, i_a—or rather inertia and momentum, i^a—and radius vector, g^a. The components of this bi-vector are given by the determinants of the matrix

$$\left|\begin{matrix} i^{(0)} & i^{(4)} & i^{(2)} & i^{(3)} \\ g^{(0)} & g^{(1)} & g^{(2)} & g^{(3)} \end{matrix}\right|, \text{ say } A^{ab} = \left|\begin{matrix} i^a & i^b \\ g^a & g^b \end{matrix}\right|. \qquad (4, 1)$$

Take the sum of the bi-vectors of two particles, or of any number of particles, and we shall have the bi-vector

$$M^{ab} = \Sigma_{(n)} A^{ab}_n, \qquad (4, 2)$$

with six components, of total moment of momentum. Three of these components (for $a = 0$) define the moment of inertia relative to the origin.

The *inertia centre* must be defined as the *locus of origins* in time-space such as to make the moment of inertia vanish. To make the definition invariant, we require the moment of inertia to vanish in a Lorentz frame where the total energy-momentum vector is directed purely parallel to the time axis, so that *there is no resultant momentum*. Thus

$$M^{0b} = 0, \quad (b = 1, 2, 3) \qquad (4, 3)$$

In all other frames, that is, for a system of free particles showing resultant momentum, *we shall then find* a moment of inertia or, say, *a polarization of inertia*.

For any number of particles, first define $I^a = \Sigma_{(n)} i^a_n$. The determinants

$$P^{abc} = \Sigma_{(n)} \left|\begin{matrix} g^a_n & g^b_n & g^c_n \\ i^a_n & i^b_n & i^c_n \\ I^a & I^b & I^c \end{matrix}\right|, \qquad (5)$$

will represent the components of the tri-vector of *internal moment of momentum, multiplied by the magnitude of I.*

The dynamical variables here given were first published in 1927[1], and an illustration of the polarization of inertia is offered in the example of a rolling hoop[2] and a rotating ring[3].

A. D. FOKKER.

Teyler's Stichting,
Haarlem.
April 23.

[1] *Physica, Ned. T. Natuurk.*, **7**, 330 (1927). Fokker, "Relativiteitstheorie" (Groningen: Noordhoff, 1929).

[2] *Physica, Ned. T. Natuurk.*, **1**, 35 (1921).

[3] Nuyens, M., *Physica, Ned. T. Natuurk.*, **9**, 181 (1929).

WE regret having overlooked Prof. Fokker's publications on the subject of the mass centre in relativity. His definition of the centre of inertia does not coincide exactly with our definition of the mass centre. Which definition is to be preferred depends, of course, on the use which can be made of it.

Our purpose was to separate from the Hamiltonian of a system of two particles that term which corresponds to the motion of the system as a whole, and to do it in such a way that the new variables form canonically conjugate pairs. We have shown how this can be done for two free particles by introducing the total momentum **P** and the internal momentum π; the canonically conjugate variables are **R** and ρ, as mentioned in our previous letter, though we did not give explicit expressions. Here **R** is to be interpreted as representing the position of the mass centre.

We have compared the two definitions and found that the mass centre coincides with the centre of inertia in the Lorentz system in which the total momentum vanishes. The two centres are therefore to some extent equivalent.

Although we readily agree that Prof. Fokker's definition is formally much more elegant, we cannot see that it is helpful for the quantum mechanical problem which we had in mind.

Properties of Cytochrome *c*

A STRONG solution of pure cytochrome *c* obtained by the method which we have previously described[1] shows in the oxidized state an absorption spectrum of the parahæmatin type. In a very much higher concentration and in a thick layer this compound reveals the two additional feeble absorption bands at about 695 mμ and 625 mμ discovered by Yakushiji[2]. The absorption spectrum of oxidized cytochrome *c* changes with the hydrogen ion concentration[2,3]. In this respect, cytochrome *c* resembles other trivalent hæmatin compounds such as methæmoglobin, parahæmatin and hæmatin. It is known, for example, that a parahæmatin compound has a characteristic absorption spectrum only within a certain limited range of hydrogen ion concentration[4]. On acidifying it or on making it alkaline the absorption spectrum of parahæmatin changes respectively to those of free acid and free alkaline hæmatins.

Although in acid solution cytochrome *c* shows an absorption spectrum similar to that of a free acid hæmatin with a characteristic band at 625 mμ, in a strongly alkaline solution, instead of showing the spectrum of a free alkaline hæmatin, it shows the spectrum of a parahæmatin.

On reducing cytochrome *c*, in either strongly acid or strongly alkaline solution, a compound is invariably obtained with the typical absorption spectrum of reduced cytochrome *c*. The absorption spectrum corresponding to that of a free hæm of cytochrome *c* has not so far been observed.

Interesting changes in the absorption spectrum of cytochrome *c* can be observed by treating it with sodium dodecyl sulphate (S.D.S.), a powerful surface active substance previously used in connexion with the study of other proteins[5]. On mixing 1 c.c. of a strong solution of *c* with 0·1 c.c. of 5 per cent neutralized solution of S.D.S., the absorption spectrum of parahæmatin is rapidly replaced by that of acid hæmatin. However, sodium hyposulphite reduces this compound, not to the ordinary reduced cytochrome *c*, but to a derivative showing two feeble and more diffuse bands at 563 mμ and 530 mμ, of which the first is stronger than the second. This derivative is autoxidizable, and forms with carbon monoxide a stable compound with absorption bands at 562 mμ and 532 mμ, the second band being now as strong as the first.

The effect of S.D.S. on cytochrome *c* is reversible, as after removing this reagent by dialysis cytochrome *c* reverts to its original state. On the contrary, S.D.S. added to a colloidal heart muscle preparation containing the complete cytochrome system clarifies this preparation and irreversibly destroys all the components of the system except *c*.

The absorption spectrum of the divalent derivative of *c* obtained in this way resembles that of a free hæm. On the other hand, the fact that it cannot be separated from its protein by either fractional precipitations, adsorptions or ultrafiltration shows that the hæm nucleus is still bound to the protein.

This derivative can therefore be considered as a hæm-protein compound, in which the protein has probably lost its connexion with the iron although it remains still linked with the porphyrin.

A similar compound can be obtained from methæmoglobin not treated with S.D.S. but acidified until the bands of acid hæmatin appear. On reduction with sodium hyposulphite this derivative, instead of forming hæmoglobin or hæmochromogen, gives a compound with the absorption spectrum of a hæm. On the other hand, when methæmoglobin is treated with S.D.S. it turns at once into a parahæmatin, which on reduction gives an ordinary globin hæmochromogen.

These observations strongly support the view that the protein and the prosthetic group in cytochrome *c* as well as in other natural hæmatin-protein compounds are bound by means of several links of very unequal stability and which are affected reversibly or irreversibly by different factors modifying simultaneously the general properties of these compounds.

The nature of these links in cytochrome *c* is, however, far from being understood, and this is not surprising considering how very little is known of the nature of links uniting hæm with globin in the hæmoglobin molecule.

A Crystalline Albumin Component of Skeletal Muscle

THE intracellular protein components of skeletal muscle are known generally as myosin, globulin *X*, myogen and myoalbumin. Myosin, the globulin which is probably directly related to the contractile process, is the major component, according to analyses carried out on rabbit and fish muscle. The remaining components have not been well characterized as individual proteins. For this reason it seemed desirable to attempt the crystallization of muscle albumin (myogen), adopting the technique employed by McMeekin[1] for the separation of the serum proteins.

A CRYSTALLINE ALBUMIN FROM RABBIT MUSCLE. (*c*. × 260.)

The crystalline albumin eventually obtained from rabbit muscle was crystallized from ammonium sulphate solutions of molarity 2·7–3·1 (65–75 per cent saturated) adjusted to *p*H 5·8 with sulphuric acid. Crystals identical in form have been obtained both from the potassium chloride extract employed by Edsall[2] for the preparation of myosin and also from muscle press juice. They consist of thin colourless plates, birefringent in polarized light, and exhibiting a pronounced sheen on agitation. The protein readily denatures on heating to 50°, by shaking, or by reducing the acidity to *p*H 5. Its iso-electric point is near *p*H 6.

Sedimentation and diffusion experiments on the crystal sample shown in the accompanying figure have been carried out through the kindness of Dr. E. J. Cohn, of the Harvard Medical School. They indicate a molecular weight of 155,000, a value which is provisional until other samples have been analysed.

During the course of this investigation, carried out in the summer of last year at the Woods Hole Marine Biological Station, Mass., Baranowski[3] reported from the laboratory of Parnas the crystallization of two albumins, myogens *A* and *B*. These he obtained from that fraction of press juice precipitating between 40 and 60 per cent saturation with ammonium sulphate. Myogen *A*, crystallizing in the form of hexagonal bipyramids, was studied in some detail, and Gralén[4], from sedimentation and diffusion experiments, assessed its molecular weight at 150,000. Myogen *B*, on the other hand, was sometimes fortuitously obtained from the mother liquors, and no method could be given for its preparation. Although our albumin separates at somewhat higher ammonium sulphate concentrations than those employed by Baranowski, it seems probable from his description that myogen *B* and our protein may be identical. To none of these albumins has any physiological activity as yet been assigned.

Further studies on the albumin will shortly be resumed.

Thyroid Gland and Potassium Metabolism

IN experimental thyrotoxicosis as well as in Graves' disease, there is a marked disturbance of the carbohydrate metabolism. The sugar tolerance is often lowered and glycosuria may develop. Griffiths[1] reports that in cases of Graves' disease a high-grade insulin insensitivity may be found, and that such insensitivity is diminished by thyroidectomy. It is also well known that after administration of thyroid gland or thyroxine the liver glycogen disappears and cannot be restored by administration of sugar[2].

In recent years a close correlation has been found between potassium metabolism and carbohydrate metabolism[3]. It was now established that in experimental thyrotoxicosis the carbohydrate metabolism and the potassium metabolism are both affected. This is especially true with regard to the potassium and carbohydrate content of the liver. The liver of normal white rats contains about 1·7 per cent potassium. Administration of thyroid hormone causes a rise in liver potassium to 3–5 per cent and more, varying with the degree of thyrotoxicosis.

As with adrenalectomized animals, the hyperthyroidized animals are very sensitive to a high potassium intake. A food rich in potassium produces in hyperthyroidized animals a rapid fall of the body weight, loss of appetite, accompanied by a high degree of excitability and finally death.

It seems that, besides the adrenal cortex, the thyroid gland is also involved in the regulation of the potassium metabolism.

Effect of Radiations on Bacteriophage C_{16}

IT has been shown previously[1] that the effect of X-rays on phages is in relation to particle size, as determined by ultra-filtration and ultra-centrifugation analysis: the larger the particle size, the greater is the sensitiveness of the phage to radiation.

We have undertaken a quantitative analysis of this phenomenon, and are dealing here with the effect of different radiations on phage C_{16} (F. M. Burnet)[2], which is active on dysentery bacillus Y_{6R}. Its diameter, as determined by Elford and Andrewes, is 50–75 mμ.

The following radiations have been used: (1) monochromatic X-rays of 17 kv. (K_α line of molybdenum); (2) non-monochromatic hard X-rays (D.C., 200 kv.); (3) total radiation of radon + active deposit, dissolved in the phage suspension. The effects on the phage were followed by the plaque count method, which

practically corresponds to counting the number of active particles present in the samples[3].

The results, shown in the accompanying table, may be summarized as follows:

(1) For all the radiations used, the proportion N/N_0 of active particles diminishes exponentially as dose D increases:

$$N/N_0 = e^{-\sigma D}. \quad (1)$$

It will be seen from the table that the values N/N_0 experimentally found are in very good agreement with those calculated on the assumption of an exponential law.

(2) The effect of radiations on phage is a function of the dose $D = I.t$, and does not depend on its components I (intensity) and t (time of exposure).

(3) The doses of X-rays being expressed in r units ($lr = 2 \times 10^9$ ions/cm.^{3} in air), equal doses of different wave-length rays produce the same effect.

(4) With α-particles a dose[4] seven times larger than with X-rays must be used in order to produce the same effect.

These results can be explained in terms of the 'target hypothesis'[5], in the following way.

A phage particle is inactivated by a single 'hit', as shown by the exponential inactivation rate. The independence of the wave-length in the case of X-rays shows that this hit is an elementary ionization process (single ionization, or (Jordan[6]) small groups of 2·2 ions in the average).

The relationship (1) allows us to calculate the value of σ. If we express the doses in ions (or in ion groups) per volume unit, σ has the dimensions of a volume ('action volume'): all the ionizations produced in this theoretical volume—and those only—are effective. In the case of X-rays the action volume has a radius of 14 mμ (doses expressed in ions) or 18 mμ (doses in ion groups). With α-particles the radius is reduced to 7·5 mμ (doses in ions).

In comparing the dimensions of the phage particles, as determined by ultra-filtration and ultra-centrifugation, with the calculated action volume, it should be borne in mind that the latter are by themselves but expressions of probability: we may imagine, for example, an action volume σ',n times larger, in which an ionization process is followed by inactivation with a probability $p = 1/n$; ($\sigma = p\sigma'$).

However, the fact that the calculated action volume is smaller in the case of radiations which produce a very dense ionization (α-particles), shows that the action volume corresponds to a really existing 'sensitive volume'[6]. When the distance between two ionizations is smaller than the dimensions of this sensitive volume, a part of the ionization process is ineffective for the biological action: correspondingly more energy must be absorbed, in order to produce the same effect. The sensitive volume will have, as lower limit, the dimensions of the action volume calculated for hard X-rays, and will be equal to it, if $p = 1$.

On the other hand, in the case of the very densely ionizing α-particles, it seems reasonable to think that the collision of such a particle with the sensitive volume is surely an effective 'hit'. Then, if we express doses in α-trajectories per surface unit, the value of σ from relationship (1) gives us the cross-section for this collision. The cross-section would have a radius of about 50 mμ. Deducting from that the radius of the ionization column produced by the α-particle (about 20 mμ; Jordan[7]), we find for the sensitive volume a radius of 30 mμ, in rather good agreement with the radius of the phage particles as given by ultra-filtration.

On the whole, our results tend to prove that phage inactivation is an elementary quantic process. They are in agreement with the view that phages, as well as certain viruses, are monomolecular structures: the inactivation should be conceived as a quantic transition of such a molecule. In this respect, our results are closely similar to those obtained by Timofeeff-Ressovsky[8] on gene radio-mutations in Drosophila.

Nitrogen Fixation in the Rice-Field Soils of Bengal

It has been proved by several workers by means of pure culture experiments that fixation of atmospheric nitrogen may take place by the activity of some algæ, specially members of the group Myxophyceæ. On the mucous sheath of most of these algæ bacteria are generally present quite abundantly. Many of these are found to be Azotobacter, Clostridium and other nitrogen-fixing bacteria which are ordinarily distributed in the soil. Pure culture technique has been employed by recent workers to find out whether the bacteria and the various algæ by themselves independently or jointly (symbiotically) carry on nitrogen-fixation work.

Kossowitsch[1], using pure cultures, came to the conclusion that nitrogen-fixation could not be carried out by the algæ by themselves, but only when contaminated by bacteria, and suggested a symbiotic relation. Similar conclusions were arrived at by Bouilhae[2], Bouilhae and Giustiniani[3] and Schramm[4]. On the other hand, Molisch[5] isolated a pure Nostoc which could grow in a nitrogen-free solution. Allison and Hoover[6], Allison, Hoover and Morris[7] and Copeland[8] have ascribed power of nitrogen fixation to Nostoc, and to other Myxophyceæ. In India, the presence of algal scum in water-logged paddy fields has been found by Sen and others[9], working with alluvial soil of Faridpur, Bengal, to be associated with increase in nitrogen content. All workers agree that the agency responsible for fixation of nitrogen in these soils is of a biological nature. Recently Fritsch and De[10] and De[11], using bacteria-free unialgal cultures of certain Myxophyceæ isolated from soil samples taken from Faridpur rice fields, came to the conclusion that a considerable quantity of atmospheric nitrogen was fixed by some of these Myxophyceæ and even when these were mixed with Azotobacter, the amount of nitrogen fixed did not increase; hence they concluded that the bacteria play a relatively unimportant part in nitrogen-fixation in the rice-fields.

Working with soil samples from the same paddy fields of Faridpur, sent to me by Sir Bryce Burt, I came to somewhat different conclusions[12]. I found that quite a considerable amount of nitrogen was fixed by the Azotobacter isolated from the mucous sheath of the algæ growing on these soils and that the amount of nitrogen fixed did not increase when the contaminated algæ were put in the culture flasks. From observations in the paddy fields, I conclude that the algæ play a relatively unimportant part in a direct manner in fixing atmospheric nitrogen in the rice fields, but indirectly this action is of the highest importance.

When the algæ die, they provide an enormous mass of growth medium on which these bacteria thrive so well. The limited number of bacteria present in the mucous coat of these Myxophyceæ now start rapidly multiplying. The conditions for growth are very favourable at this time and a large quantity of nitrogen is now fixed by these well-known nitrogen-fixers, leading to the increase of nitrates in these soils. When under favourable conditions the algæ were multiplying, much of the nitrate formed was utilized by the algæ themselves. It is only after the death of the algæ (and it may be mentioned that they die *en masse* when the water begins to dry up and the fields are not flooded any more after the crop has been harvested) that this rapid multiplication of bacteria takes place leading to the enormous increase of soil nitrates. Thus the action of these algæ in the matter of nitrogen-fixation in the rice-fields of Bengal is, I believe, indirect, the bacteria being primarily responsible for the fixation of the atmospheric nitrogen.

Salt Accumulation and Plant Respiration

THE recent discussions in NATURE between Lundegårdh[1,2] and Hoagland and Steward[3,4] have shown that Lundegårdh's conclusions, based on his own experimental results, are not acceptable to Hoagland and Steward, who have used other types of plant material and a different technique. While it would be surprising if the results obtained with one type of plant material could be replicated exactly for other types, Lundegårdh's suggested mechanism may be applicable to other tissues; Hoagland and Steward do not succeed in disproving Lundegårdh's interpretation of his data. In view of the fact that Hoagland and Steward found it necessary to suspend judgement on the reality of the anion respiration coefficients on which Lundegårdh's conception largely depends, the following data are of interest.

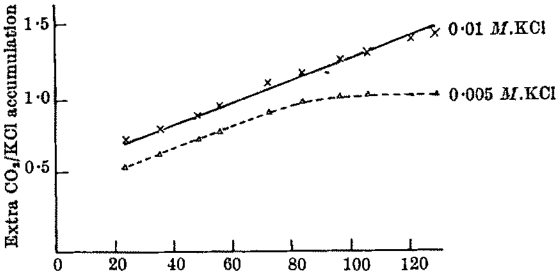

Fig. 1.

Recent work in this laboratory on cut carrot tissue under controlled conditions gives qualitative support to Lundegårdh's conclusion that there is a definite relationship between the amount of salt accumulated and the extra carbon dioxide evolved. The relationship, in carrot tissue, differs quantitatively from that obtained by Lundegårdh with other plant material. According to Lundegårdh's interpretation

$$R_T = R_G + kA,$$

where R_T is the total respiration, R_G is that respiration which occurs independently of the mechanism of ion absorption and kA is the anion respiration which is a multiple, k, of the anion absorption A. In the work done in this laboratory with carrot tissue, the net amounts of different metallic chlorides accumulated and the total carbon dioxide evolved were

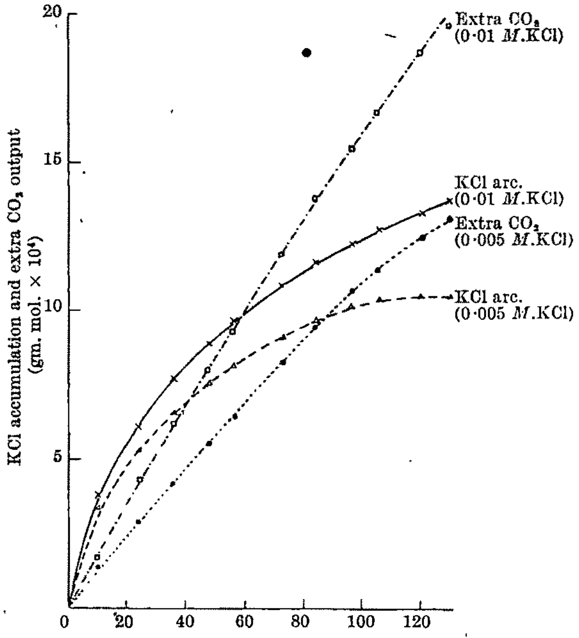

Fig. 2.

THE KCl ACCUMULATION AND EXTRA CARBON DIOXIDE OUTPUT FOR TWO COMPARABLE SETS OF TISSUE, UNDER CONTROL CONDITIONS, ONE IN 0·01 *M*.KCl AND THE OTHER IN 0·005 *M*.KCl. ACCUMULATION FROM THE MORE DILUTE SOLUTION CEASED WHEN ALL THE KCl WAS ABSORBED AFTER ABOUT 120 HOURS.

simultaneously determined. Taking the carbon dioxide production due to the salt as the total in the presence of salt less the total in distilled water, the ratio $\frac{\text{salt respiration}}{\text{salt absorption}}$ can be obtained. This is the same as Lundegårdh's k though its absolute value may differ slightly if, as Lundegårdh suggests, the respiration in distilled water is not the same as the R_G. This ratio, unlike that obtained by Lundegårdh, has not been found to be "fairly constant if the anion absorption is varied by variation in the concentration of a single salt". The ratio varies both with concentration absorbed and with time.

It is seen (Fig. 1) that the ratio increases from 0·75 in the early stages to 1·5 in the later stages and remains constant only when, as in the case with the 0·005 $M.$ solution, all the salt has been absorbed from the external solution. The reason for the increase in the value of the ratio is to be found in the decreased rate of accumulation of the salt with time. The rapid initial accumulation, followed by a lower rate of accumulation which changes only slightly over a long period, has been established as characteristic of carrot tissue (Briggs and Robertson)[5] and is similar to that obtained with high salt barley roots (Hoagland and Broyer)[6]. The respiration, having reached its maximum within two hours of the addition of the electrolyte, decreases negligibly during the rest of the experiment (Fig. 2). In the case of the lower concentration of salt, the carbon dioxide production remains high in spite of the fact that all the salt has been absorbed. From these results it is clear that the salt respiration cannot be expressed as a linear function of A; it could be expressed as a function of A and t.

The difference between this result and that of Lundegårdh may be due to the difference in the plant tissues, but it is also possible that Lundegårdh did not obtain the same relationship because his results are all for short periods and over a concentration range where the amount absorbed is probably limited by concentration. At higher external concentrations the amount absorbed tends to be independent of concentration. The fact that the ratio remains high even after absorption has ceased indicates that the extra carbon dioxide is related not only to the ions being absorbed but also to the internal concentration being maintained. The fact that the amount of extra carbon dioxide per amount of ions absorbed increases as the absorption falls may be in accord with Lundegårdh's idea that the more difficult it is for cations to enter, the more energy is required to balance the accumulation of the anions. Other results obtained with sodium, lithium, magnesium and calcium chlorides confirm Lundegårdh's conclusion that the ratio of extra carbon dioxide production to amount absorbed increases with the decreased mobility of the cations in the protoplasm. The divalent chlorides give much greater ratios than do the monovalent.

It is hoped to publish this work in full shortly.

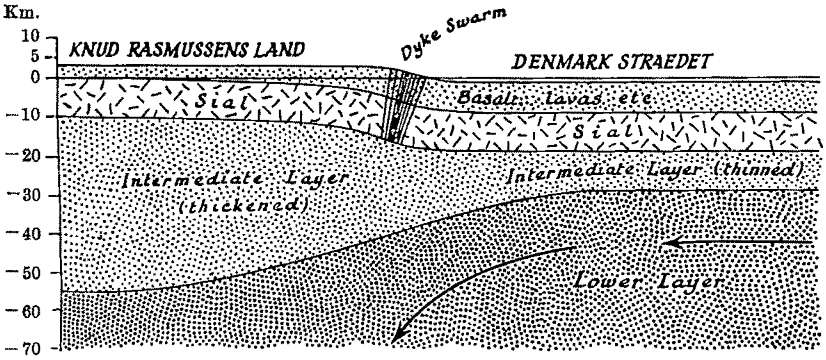
Epeirogenic Earth Movements in East Greenland and the Depths of the Earth

Satisfactory geological evidence that the earth's crust has undergone powerful vertical movements unaccompanied by horizontal compression has seldom been obtained, and Daly[1] has recently given it as his opinion that such movements have not been sufficiently well proved to be taken into consideration in attempts to understand the nature of the earth's interior. During recent expeditions to East Greenland geological mapping has shown that the coastal mountains from lat. 66–70° N. were produced by a powerful, and geologically rapid, vertical uplift. Between the Denmark Strait and the adjacent mountain belt of East Greenland the relative vertical movement of the crust amounted locally to at least 3½ km. and was but little less over the whole stretch of 800 km. Such a displacement must be regarded as a major tectonic feature of the earth's crust and merits brief description as the full account, prepared for a Danish journal, cannot be published at present.

In late Cretaceous times much of this part of East Greenland was at about sea-level and some marine Senonian sediments were laid down. These were succeeded by the extrusion of basalts which, in places, accumulated to a thickness of at least 7 km. During middle Eocene times powerful uplift took place which gave rise to what is now the highest part of coastal Greenland, while down-sinking of the area to the east gave the Denmark Strait. The rocks between these regions of opposite radial movement were bent into a flexure. During the flexuring a dense dyke swarm[2] was injected which allows the age of the earth-movements to be fixed and shows that tension then existed in the upper crust. Folding, overthrusting or other evidence of compression are entirely lacking. The widespread and powerful radial earth-movement in East Greenland, which may be described as epeirogenic since there is no evidence that it was a secondary result of tangential compression, emphasizes by its magnitude the importance of vertical crustal movements of the kind which take place without tangential compression.

Phenomena of this kind must either be left unexplained or some hypothesis must be advanced involving the deeper layers of the earth. Since so little is known about the depths of the earth a range of hypotheses is possible. For this particular case du Toit[3] has suggested one which is based on the paramorphic principle, but while this might explain the downsinking of the Denmark Strait where a great thickness of basalts accumulated, it cannot account for the uplift of the adjacent land which was also covered by basalts, though less thickly. A more satisfactory hypothesis seems to be that of migration of subcrustal material followed by adjustment to isostatic equilibrium. This view was suggested when the dyke swarm was briefly described[4], and part of the uplift was explained as a result of migration of the lower part of the sial layer. If, however, the whole of the vertical movement is to be accounted for by migration of material in depth, then it is necessary to postulate a greater movement of some subcrustal layer than was previously suggested.

At the time of these movements in East Greenland, the crust was capable of tension fracturing, at any rate where the dyke swarm was developed, and compressive forces were nowhere sufficient to cause



folding or thrusting in the visible part of the crust. The dykes occupying the tension fractures are of basaltic composition indicating that basic magma and not acid was then available. The change from a crustal layer, capable of being thickened or thinned by flow, to an overlying layer which remained unaffected is likely to have taken place where there was a sharp change of composition. For these reasons it seems likely that during the epeirogenic movement in East Greenland an intermediate layer of basaltic composition was changed in thickness, while the overlying sial layer remained unaffected (see accompanying illustration). The migration of material may have been effected by the drag of convection currents in a lower layer; several indirect lines of evidence, recently summarized by Gutenberg[5], now suggest the existence of such currents.

The process described above is capable of producing by direct sinking an ocean basin such as the North Atlantic, and yet it is not at variance with the theory that the earth's crust is in isostatic equilibrium. New evidence for the hypothesis that the North Atlantic has been formed in part by direct sinking is provided by the recent work on submarine geology and topography summarized by Field[6].

Surnames, Intelligence and Fertility

IN a recent communication[1], Prof. R. A. Fisher and Dr. Janet Vaughan showed that a significant racial difference in blood-group frequencies could be detected in a sample of Liverpool donors by comparing with the whole group those possessing characteristically Welsh family names. This has prompted me to make a similar comparison for intelligence, as estimated by a mental test, in the case of a practically complete sample of school-children living in the city of Bath. The results may be of interest in view of the scarcity of observations made under conditions likely to ensure a fair comparison of racial groups. Furthermore, it has sometimes been suggested that Welsh immigrants in English cities tend to be of lower average intelligence and greater fertility than the native populations; in this connexion see, for example, Cattell[2].

The sample of Bath schoolchildren consists of those whose dates of birth fell between September 1, 1921, and August 31, 1925, inclusive, and who were living within the city boundaries on July 27, 1934. Extremely few children escaped the ascertainment and mental testing; full details have been published[3]. The scale used was the Advanced Otis and the results are expressed in terms of an 'Index of Brightness', or *I.B.*, which is simply a device for adjusting scores so as to allow for varying age at test. The norms were established on the group itself. The number of children is 3,361.

For the selection of Welsh family names I am much indebted to Mr. B. S. Bramwell, of the Society of Genealogists. In a paper[4] in which he made certain interesting racial comparisons he used family names for differentiating groups. He gave a list of 33 characteristically Welsh names. Of these, 24 are represented in the index of Bath children: Davies, Edwards, Evans, Francis, Harris, Hughes, James, Jenkins, Jones, Lewis, Lloyd, Morgan, Morris, Owen, Parry, Phillips, Powell, Price, Pritchard, Richards, Roberts, Thomas, Williams and Willis. To increase the numbers I submitted to Mr. Bramwell a further list of names taken from the Bath index. Of these he selected ten: Griffiths, Howell, Howells, Humphries, John, Owens, Probert, Pugh, Rice and Vaughan. The number of children bearing these family names is 213, 6·3 per cent of the whole group.

COMPARISON WITH THE REMAINDER OF CHILDREN BEARING WELSH FAMILY NAMES.

	No.	Mean Otis *I.B.*	Standard deviation	Standard error of mean
Welsh family names	213	102·9	36·4	2·5
Remainder	3148	99·8	34·7	0·6

The difference in mean performance, 3·1, is not significant, being only 1·2 times its standard error. The difference between the standard deviations is not significant either, being less than its standard error. The frequency curve for the children with Welsh names is closely similar to that for the remainder, and does not depart significantly from the normal form.

In regard to fertility, taking as a measure the number of living full brothers and sisters (at the time the information was obtained), the Welsh children have an average of 2·46 sibs, while the remainder have 2·59. The difference is not significant. (Full data have recently been published[5] on the fertility of Welsh migrants in the city of Oxford.)

It can safely be concluded that whatever racial characteristics distinguish the Bath citizens who are of Welsh origin, a lower average level of general intelligence and a higher fertility are not among them.

History of the Vacuum Flask

WHILE fully accepting all that Mr. Gabb writes in NATURE of June 1 about matters of fact within his knowledge, I am still of opinion that Lennox made the first vacuum test tubes and flasks by methods of his own. Those I saw on his bench were transparent (unsilvered), and, having watched both him and Muller at work, I consider that he was quite as capable of doing it as Muller.

My father's assistant, Gordon, who was working at the Royal Institution at the time, clearly stated to me that Lennox arrived at his methods by trials which he, Gordon, had witnessed.

Mr. W. J. Green, of the Royal Institution, writes to me (May 2, 1940):

"Mr. Heath [Dewar's second assistant] told me quite definitely that Lennox made the first vacuum vessels in the laboratory, and further that he passed on his methods to outside people who were asked to supply in addition to what the laboratory could make."

Photolysis of Acetaldehyde

IN a recent paper on the high temperature (300° C.) photolysis of acetaldehyde[1], it is suggested that earlier work[2] based on measurements of pressure change may be unreliable on account of possible polymerization.

We have followed the course of this photolysis by chemical analysis for acetaldehyde at various stages, using the method of Friedemann, Cotonio and Shaffer[3]. The rate of decomposition of the aldehyde measured in this way agrees exactly with the observed pressure change, as is shown in the following example:

Initial acetaldehyde pressure: 100 mm. Temperature: 300° C.

Time (min.)	Observed pressure change (mm.)	CH_3CHO decomposed (by analysis)
0	0	0
1	+ 6·7	6·8
2	+ 12·8	12·7
3	+ 17·3	17·1
4	+ 20·5	21·0
5	+ 25·0	25·0

These results, coupled with the fact that a pressure increase of practically 100 per cent is observed on prolonged irradiation, shows that no appreciable polymerization takes place under these conditions. There is hence no reason to doubt the accuracy of the earlier work.

Points from Foregoing Letters

Using a new oil-drop method, T. H. Laby and V. D. Hopper have made a new determination of the electronic charge. They claim for the results a probable error one third of that of Millikan's determination, and state that it agrees with the value of the electronic charge by the X-ray method to the accuracy with which the viscosity of air is known.

A. D. Fokker, after indicating the dynamical variables for a system of two particles in relativity theory, presents Lorentz-invariant definitions for the centre of inertia and for the internal moment of momentum of a system of any number of free particles.

On treating cytochrome *c* with sodium dodecyle sulphate (S.D.S.) D. Keilin and E. F. Hartree find that a derivative is obtained which can be considered as a hæm-protein compound, in which the protein has probably lost its connexion with the iron although it remains still linked with the porphyrin. The effect of S.D.S. on cytochrome *c* is reversible, as after removing this reagent by dialysis cytochrome *c* reverts to its original state.

K. Bailey reports the crystallization of an albumin from rabbit muscle. Although obtained independently, it may be identical with the myogen *B* which Baranowski has occasionally obtained in the mother liquors of myogen *A*.

E. Wollman, F. Holweck and S. Luria have subjected a bacteriophage to the effects of various forms of radiation. Their results lead to the conclusion that inactivation of bacteriophage by irradiation is a quantum effect, and that the phage is a monomolecular structure.

Referring to recent work suggesting that certain algæ, particularly algæ from Indian rice fields, are able to fix atmospheric nitrogen, H. Chaudhuri states that his own work leads to the view that bacteria, living in the mucous sheath of these algæ, are responsible for nitrogen fixation.

R. N. Robertson, working on salt accumulation and respiration in cut carrot tissue, finds that the ratio of carbon dioxide produced in the presence of salt to the amount of salt absorption varies with concentration of salt absorbed and with time. His work supports Lundegårdh's views in relation to ionic absorption.

L. R. Wager describes a powerful Eocene flexure of the earth's crust which has recently been found in East Greenland. He suggests that it has resulted from variation in thickness of an intermediate layer of basaltic composition under the influence of convection currents.

In the high temperature photolysis of acetaldehyde C. J. Danby finds that the course of the reaction as followed by chemical analysis agrees exactly with the observed pressure change, which therefore gives an accurate measure of the reaction rate.

RESEARCH ITEMS

Shamanism in the South-West United States

AN account by Isabel T. Kelly of shamanism as practised by seven of the original fifteen bands of the Southern Paiute (*Anthrop. Rec.*, 2, 4, Univ. California Press, 1939) is based on field observations occupying eleven months in 1932–34. They are sufficiently full to permit formulation of a characteristic Paiute pattern, while bringing out local specializations. The outstanding common features may be outlined as follows. Shamans of either sex derive their powers from dreams, usually unsolicited. They confer with a familiar spirit, sometimes human, more frequently animal, from which they receive songs and instruction for curing. Neither powers, songs nor office are inherited. Sickness is attributed to intrusion of a material object or a ghost, or less commonly to soul loss. The last is cured by pursuit and restoration of the lost soul, the two former by sucking and song. All bands distinguish between the rattlesnake shaman and the general practitioner, and some recognize numerous other specialists. Paucity of material makes it difficult to place Southern Paiute shamanism with respect to that of either the Great Basin or other adjacent areas. Object intrusion is nearly universal in western North America in contrast to the relatively infrequent ghost intrusion. Emphasis on the guardian spirit is reminiscent of central California, while the idea of soul loss calls to mind Southern California. The closest specific resemblance is with the Havasupai. The difficulty of delimiting Southern Paiute with respect to surrounding areas is perhaps as significant as any other fact in evaluating it as characteristically Basin.

Aluminium Dust in Silicosis

SILICOSIS, the lung disease to which stone cutters and others who work in dusty trades are subject, has been noticed to develop in rabbits exposed to air containing moderate concentrations of fine quartz particles. In the *Bell Laboratory Records* of April, it is stated that this is completely prevented if there is as little as one hundredth as much aluminium dust as silica in the air breathed. This preventive action was discovered at the McIntyre Porcupine Mines, and has been ascribed to an extremely thin coating of an aluminium compound deposited on the silica particles. The action of the aluminium is sufficiently curious and important to justify a fuller understanding of the nature of the film which it forms upon quartz particles. Dr. Frary, director of the Aluminium Research Laboratories, suggested that the answer might be forthcoming if a study were made of electron diffraction patterns. In experiments carried on by L. H. Germer and K. H. Storks, a beam of high-speed electrons was passed through thin films of silica which had previously been exposed to aluminium and water at body temperature. The diffraction patterns obtained showed a layer of aluminium hydrate less than one millionth of an inch thick on the silica. Although extremely thin, this layer is sufficient to prevent the silica from injuring the lungs. Two very striking photographs are shown of electron diffraction patterns, one of aluminium hydrate on silica and the other of silica alone.

Medical Uses of Radium

THERE are probably not many who have been consecutive readers of the seventeen yearly reports, "Medical Uses of Radium", published by the Medical Research Council since 1923. They are interesting in retrospect as showing the gradual emergence of radium treatment from a qualitative to a quantitative basis, and in bringing to the reader the conviction that radium, properly used, is a valuable agent in the treatment of cancer and several other non-malignant conditions—witness the statistical data, evidently prepared with great care, which figure throughout the text of the current report (Spec. Rep. Ser. No. 236). The research side of this work under the ægis of the Council has grown year by year; only to enumerate the titles of the research work of different centres will give an idea of the way in which the science and art of radium treatment are being strengthened. These lines of investigation include studies upon artificial radioactivity, irradiation of gels and the polymerization of liquids, biochemical effects of radiation, the dependence of biological effects upon the wave-length, the concentration of radon at which it becomes harmful, the production of mutations in Drosophila and the formation of malignant growths in the rabbit as a result of prolonged radiation—such are the varied researches contributing to the growth of this subject.

Teart Disease in Cattle

A LARGE area of pasture in central Somerset and smaller areas elsewhere have been known for more than a century to cause scouring in ruminants, especially cows in milk and young stock. Such land in known locally as 'teart'. During the past four years an intensive study of the problem has been made by W. S. Ferguson, A. H. Lewis and S. J. Watson, and their results are now published in Bulletin No. 1 of the Jealott's Hill Research Station (Imperial Chemical Industries, Ltd.), Bracknell, Berks. The cause of teartness is the presence in the herbage of molybdenum, which is highest in green leafy material, particularly clovers and Yorkshire fog, considerably less in hay and very low in dead or frosted herbage. The land, therefore, can only be grazed with safety during the winter, and 'improvement' of the pasture only aggravates the trouble owing to the increase in clover. Scouring, however, can be entirely cured and prevented by feeding or drenching the stock with copper sulphate. 2 gm. per cow per day or 1 gm. for young stock is sufficient. Experiments conducted in America show that copper sulphate fed continuously at the above rates for a long period is not likely to have any harmful effect on stock. Experiments are in progress to see if the addition of copper compounds to the soil would be equally effective. As teartness increases under neutral or alkaline conditions, basic slag and lime should not be used; but sulphate of ammonia and ammonium phosphate fertilizers can be applied with safety. Reduction of teartness is also obtained by ploughing out and reseeding, and many of the affected pastures are being converted into arable land at the present time. Shallow ploughing is suggested to avoid bringing up the more teart subsoil.

Fauna of the Belgian Cretaceous

IN a recent memoir ("La Transgression albienne et cénomanienne dans le Hainaut", *Mém. Mus. Roy. d'hist. nat. Belgique*, No. 89 ; 1939) Dr. R. Marlière gives a monograph of the fauna of the Meule de Bracquegnies, followed by an account of the characters, distribution and stratigraphical relations of the Albian and Cenomanian deposits of Hainaut. The Meule de Bracquegnies rests on Carboniferous or Wealden, and is overlapped by Cenomanian and Turonian deposits ; its fauna was described by Briart and Cornet in 1868, and the present author makes many additions to their work. Except for the absence of ammonites, the fauna resembles closely that of the Blackdown Greensand, which is of the age of part of the Upper Gault. The lamellibranchs and gastropods, which form almost the entire fauna, are such as would live on the continental shelf in water of no great depth ; they include some dwarfed forms, which, in connexion with the almost entire absence of cephalopods, brachiopods and echinoderms, suggests some peculiarity in the composition of the sea water or in the nature of the sea floor.

Flora of the Belgian Lower Devonian

THE oldest fossil plants are scrubby little things that would scarcely be looked at twice if they came from a later formation, yet their study has been characterized by the utmost care and determination of the investigator to make the specimens yield every shred of information, and one might add by first-rate photography. The first account, apart from some piecemeal work, has just been published of the Lower Devonian flora of Belgium, and it at once makes it one of the richest (with about 25 species) and best known of its period ("Végétaux Éodévoniens de la Belgique", by F. Stockmans, *Mém. Mus. Roy. d'hist. nat. Belgique*, No. 93). Really well preserved plants like those of the Rhynie Chert have yet to be found in the Lower Devonian, but many interesting new points are added in this paper to the knowledge of these little-known types, particularly to Taeniocradia, in which sporangium-like organs are described. Petrified axes of the seaweed-like Prototaxites and with it, as usual, the enigmatic sphere Pachytheca (held by some to be a fish's eye and some an alga) are described from this region also, but they do not seem to occur much in association with undoubted land plants.

Classification of Pears

IN a preliminary report (*J. Pom. and Hort. Sci.*, **18**, 52 ; 1940) M. B. Crane and D. Lewis have described a system for the classification of cultivated pear varieties, based on the morphological characters of leaves and shoots. The characters used have been shown by breeding experiments to be genetically controlled, and though some of them show seasonal variations, they can be used with confidence when the range of variations is known. Leaf-margin, midrib, shoot-hairiness and shoot and leaf colour are the characters concerned. Spur-leaf margins may be toothed, serrate-crenate, or entire. Leaf midrib may be glandular or without glands, the mean number per leaf being characteristic for a variety. Shoots may be red-purple or green, and hairy, sparsely hairy or glabrous. Leaves are either green or pale green. All these characters are reliable and not affected by rootstock. It is hoped eventually to include flower and fruit characters in the classification.

Irregular Division of the Centromere

C. D. DARLINGTON (*J. Genetics*, 39, 351–361 ; 1940) has analysed the chromosomes of species of Fritillaria and shown that chromosomes with telocentric centromeres arise by a transverse division of the centromere in a two-armed chromosome. Such telocentric chromosomes may give rise to iso-chromosomes by the chromatids opening out to form a two-armed chromosome. The author discusses the effect of these phenomena on the mechanical properties of the chromosome.

Infra-Red OH Band and Association

WITH different concentrations of ethyl alcohol in CCl_4 or CS_2, the variations in location and intensity of the bands near $3\,\mu$ have been investigated at various temperatures by J. Errera and his collaborators (*J. Chem. Phys.*, 8, 63 ; 1940). The band (3638 cm.$^{-1}$), due to single molecules, shows no alteration in intensity with concentration changes but increases in intensity at higher temperatures, whilst the band ($\simeq$ 3300 cm.$^{-1}$), due to polymeric molecules, increases in intensity with increased concentration and diminishes with increased temperature. With concentrated solutions (2–8 per cent C_2H_5OH), increased temperature causes a new band at 3520 cm.$^{-1}$ to appear, due to dimeric molecules. On the other hand, with dilute solutions ($<$ 1 per cent C_2H_5OH) practically no polymeric molecules are present and at high temperatures the dimerides break up to single molecules, and the spectrum shows diminution in the intensity of the dimeric band and increase in the intensity of the monomeric band. By cooling dilute solutions down to $-5°$ the band due to polymeric modifications reappears. At concentrations less than 0·12 per cent C_2H_5OH, only single molecules appear to exist. From the spectroscopic data the concentrations of the various species have been estimated. The mechanism involved in the association cannot be satisfactorily formulated ; nor can it be decided whether the association occurs as a result of electrostatic effects or from hydrogen bonding. The effect of adding acetone or pyridine to CCl_4 or dioxan solutions of C_2H_5OH has also been investigated. The spectra of these ternary mixtures exhibit bands due to single and double molecules, and to polymolecular complexes and addition compounds of C_2H_5OH with acetone or pyridine. The behaviour of solutions of HDO in D_2O and in various organic and inorganic media has been studied for the same spectral region.

The Electron Microscope at Toronto

THE electron microscope developed in the McLennan Laboratory at Toronto was described in the *Canadian Journal of Research* (A, **17**, 49 ; 1939). This paper contains a short and valuable summary of the results of other workers at the date of publication. The instrument is there described in some detail, and the problem of the steadiness of the high-tension supply is discussed. In this paper a limit of resolution of 200 A. was inferred. A more recent report on the microscope, by E. F. Burton, J. Hillier and A. Prebus (*Phys. Rev.*, 56, 1171 ; 1940), claims a resolving power of better than 60 A. This improvement is apparently largely due to the control of the illuminating beam of electrons, and the limit of resolution appears to be imposed to a large extent by the nature of the specimens rather than by instrumental factors.

A CENTURY IN THE FOREST LIFE OF NEW ZEALAND

One hundred years ago New Zealand had 63 million acres of forest; within eighty years it had been reduced to 12 million. Her woodlands had suffered the fate of those of so many other lands—they had been cut and mangled for immediate gain without any thought of the future. But unlike most lands where this had happened, the New Zealand people awoke to the danger of lost woodlands, and some thirty or forty years ago they decided to change their policy of total destruction for one of preservation and reconstruction. It came gradually, there being a period of overlapping with exploitation and replanting going on side by side. The policy to-day is wholly to preserve and replant.

New Zealand is in the fortunate position that not one part of her forests is inaccessible. The woods are within easy reach of shipping. This contributed in great measure to bring about exploitation, but this same feature will be of inestimable value when she comes to market her timber under a controlled policy.

For several years now the New Zealanders have led the world in the matter of tree-planting. In seven years alone 400,000 acres were planted. In one year 100,000 acres were planted, which is probably a record for the world. Altogether New Zealand possesses nearly a million acres of young forest.

What helped afforestation most in New Zealand was the discovery of the remarkable growth of certain introduced softwood trees. A pine which came from Monterey, California, namely, *Pinus insignis* or *radiata*, was the most remarkable of them all. This tree produces mature timber at 18–30 years of age and pulp wood at 12–14 years of age. The timber of mature trees is equal to the best Baltic pine, and has proved of immense value in making packing cases for dairy produce. It can also be pulped to make paper. One tree which was felled, aged forty-five years, fetched the very high price of £55.

Other trees which were introduced and reacted satisfactorily to the prevailing conditions were yellow pine, Oregon pine and the redwood of California. Certain poplars also have been making good growth.

The rapidity of growth attracted the attention of the business man. Companies were formed to afforest land and quick returns were obtained from the capital invested. Such a thing is almost unique in the history of forestry, timber growing being usually regarded as a State affair, since it means the locking up of capital for such a long time with very little return.

Within the last year or so the New Zealanders have again shown a great deal of wisdom by turning their attention to the trees which are native to the country. They are preserving what forests remain—8 million acres are under State control—and are trying to bring back to them their former grandeur and value.

The most famous natural tree of New Zealand is the kauri pine. Some remnants of it remain. This tree produced some of the best timber the world has ever seen. It also produced the kauri gum, great beds of which still lie in a fossil state in the soil. 15,000 tons of it are mined annually and find a ready market for making paint, varnish and linoleum. The resin from the living tree not only gives gum, but a motor-spirit is also being derived from it now.

There are other native trees such as yellow woods and the Nothofagus, the latter corresponding to the beech of Great Britain. The latter is now being tried on an experimental scale in Britain and is showing great promise. Then there is also the world-famous rimu tree. All these regenerate themselves naturally.

With such success already achieved it is little to be wondered that New Zealand is looking forward to the day when she will be a timber exporting country.

E. V. Laing.

INTERNATIONAL FISHERIES RESEARCH IN THE ATLANTIC*

The Committee of the Atlantic Continental Slope, on July 16, 1937, formed a sub-committee for the study of a technique concerning researches on the mackerel. Representatives from England, Ireland, France, Portugal and Germany were elected on the sub-committee, which met at the Plymouth Marine Laboratory during December 8–9, 1937. At this meeting discussions took place on: (1) the methods of sampling and selective action of nets; (2) biometrical data; (3) food; (4) age determination; (5) stages of sexual maturity; (6) plankton and hydrographical observations; (7) collection of early metamorphosed stages; (8) commercial statistics; (9) other researches.

Reports on the researches on the mackerel by J. le Gall and J. Furnestin (France), G. A. Steven and P. G. Corbin (England) and G. P. Farran (Ireland) show that progress has already been made along these lines. J. le Gall in France has been working on general and seasonal distribution, physico-chemical conditions, spawning, food and morphological characters. In Appendix I he gives a résumé of the known facts of the concentration before spawning, spawning periods and sexual maturity, growth and physical conditions of the environment. In Appendix II G. A. Steven and P. G. Corbin report on the work at Plymouth begun in 1936. Both French and English vessels participate in the spring drift fishery, from March until the middle of June, off the western entrance to the English Channel. The fish landed in the early part of the season are often thin, due apparently to absence of food supply.

---

* Rapport Atlantique 1937–1938 (Travaux du Comité du Plateau continental Atlantique) (Atlantic Slope Committee) publié avec l'aide de Ed. le Danois, Dr.Sc. Directeur de l'Office des Pêches Maritimes, Paris. *Rapports et Procès-Verbaux des Réunions*, **111**, Conseil Permanent international pour l'Exploration de la Mer. Charlottenlund Slot, Danemark. 1939.

When food is available the stomachs are full and later, when zooplankton is plentiful, the mackerel feed voraciously upon this and still later, after the shoals have broken up and dispersed along the shores of the shallow coastal waters, they feed mainly on small fishes.

In 1937 a series of cruises was made in the area to the west of the mouth of the English Channel to try to obtain information concerning the spawning of the mackerel and dispersal and distribution of the young stages. Results from 1938 and 1939 are incorporated in the account. It was found that the spawning is a protracted one lasting from March until July or even August, with its maximum from mid-April to mid-May. It occurs within the area of the Continental shelf, not over great depths, but mainly well off-shore. From April until July there was a gradual eastward shifting of the locality of spawning accompanied by a diminution in the number of eggs. Later on there is found to be a similar eastward drift and decrease in numbers in the young stages. This change in locality with time is foreshadowed by the movements of the shoals which support the commercial drift fishery based on Newlyn from March to mid-June, although routine examination shows that scarcely any ripe or spent mackerel are landed on the fish market before about the end of May. It appears that fishing takes place not on the actual spawning centres but on the inner (landward) edges of them where the fish that have not yet spawned are located. The spawning period of the individuals is found to be a protracted one. The first indication of the spawning condition is the presence of ripe eggs which appear on the outside of the ovary, widely scattered among unripe eggs. Later these ripe eggs pass into the lumen of the ovary, which, externally, then reverts to an unripe appearance. The ripe eggs are shed and the process recurs, possibly many times, before the ovary is fully spent. For study of age and growth-rate it was found that the otoliths carefully prepared are of more value than the scales. Consequently this otolith method has been adopted. Preliminary work shows as yet no dominating year class. Examination of skeletons for racial characters, not yet fully worked out, indicates that the only variant that can be found—the numbers of the thoracic vertebræ with 'open' hæmal arches—shows some variation from sample to sample.

J. Furnestin in Appendix III shows results chiefly on hydrography and plankton from the entrance to the Channel and waters south of the Irish Sea, and G. P. Farran in Appendix IV deals mainly with the plankton as food for the mackerel.

Besides these researches on the mackerel there are reports by J. le Gall and J. Furnestin on the sardine, plaice, and sand eel, by Fen Hsüeh on Manx herring shoals, by P. Desbrosses on the John Dory and G. P. Farran on surface temperature observations at Coningbeg Lightship on the south coast of Ireland.

AUTOMATIC SERVICE OF LONG-DISTANCE TELEPHONE CALLS

FULL automatic service for toll or long-distance telephone connexions, as they are variously termed, has been in operation in a number of European countries for some years. The administrations and operating companies of countries which have not yet adopted this service are anxiously considering methods of improving their service and reducing its cost. An important paper by W. Hatton, the technical administrator of the Bell Telephone Manufacturing Company at Antwerp, is published in the January issue of *Electrical Communication*, a quarterly journal issued by the International Standard Electric Corporation of New York, U.S.A.

When converting telephone networks of national dimensions from manual to automatic operation, certain problems arise which can be dealt with in a purely technical manner, while others cannot be solved without due regard to the reaction of the telephone subscriber. Signalling over long-distance circuits by voice-frequency currents, automatic regulation of the transmission level and other technical features of long-distance service do not directly concern the subscriber, provided that the final result is satisfactory. The manner in which charges for long-distance service are established and the form in which the monthly or quarterly account is presented are matters which have both technical and administrative aspects, and in which the subscriber is keenly interested.

To operate long-distance service on an automatic basis, calls must be charged automatically, and the method adopted for this must give complete satisfaction to the subscriber. Prior to the introduction of a system of automatic ticketing, first applied in Belgium, there appeared to be no method of charging subscribers automatically for their long-distance connexions, except by means of the message register. This 'message' method, known to the telephone world as 'time or zone' or sometimes as 'multiple metering', has its disadvantages. A summary of these disadvantages shows that some of them are serious and that business organizations would be reluctant to accept a monthly or quarterly bill without particulars of the individual charges for each of their long-distance connexions. In the case of hotels, these particulars would in most cases need to be furnished immediately on demand. The real solution would have to be one which maintains the present situation between the charges for local and long-distance tariffs (allowing each to be developed to suit their separate requirements) and which at the same time provides a record giving the date, the time of day, the duration of call and the cost of the message, preferably printed on a ticket.

From the practical point of view the design of such a system of automatic ticketing must permit of its introduction to existing exchanges with the minimum of modification to the equipment already installed and in operation. The author gives a sketch of such a system in operation in Belgium which seems to be in every way satisfactory. Although this system is quite a recent invention, there are already installed or on order 150,000 lines.

An excellent description is given by Mr. Hatton of the problems that had to be faced in designing an automatic ticketing system in three areas in Belgium, namely, Brussels, Antwerp and Malines. The urban network of Brussels contains fifteen exchanges of the rotary type, some dating back to 1922. The normal capacity is 115,000 lines, and this network furnishes a good example of the manner in which automatic ticketing can be added to existing equipments. The author states that Antwerp, Liége, Charleroi and other Belgian towns will follow the method adopted for Brussels.

The first installation of automatic ticketing was put into service in Bruges in 1936, and was rapidly followed by installations in Ostend and twelve other towns in Belgium. During the period July 1–September 15, 1937, a check of 62,000 ticketed calls revealed 80 tickets, or 0·13 per cent, bearing incomplete or incorrect details, and these results go far to prove that full-automatic methods can be applied to long-distance service with the same success as to local service.

The tickets provide the traffic department with valuable information, and also give a remarkably clear picture of the operating efficiency of the exchange. Each long-distance call is recorded whether it be an effective connexion or whether it results in "busy", "no answer", "wrong number", or "premature release". Equipment faults which might otherwise remain unsuspected and undetected are brought to light by the indisputable evidence of the ticket. Naturally, further developments in this field are to be anticipated. It may prove advantageous to use a small number of high-speed printers which are engaged only at the termination of a call.

A form of ticket may be produced which can be automatically sorted, and, ultimately, doubtless mechanized-accounting will further dispense with the need for human intervention. Finally, it is anticipated that automatic ticketing will prove immensely valuable in Europe when the development of international long-distance service on a fully automatic basis becomes possible.

ANALYSIS OF FIELD TRIALS

Variety testing forms an essential part of the work of the plant breeder and so he needs an adequate technique for the design and statistical analysis of field trials. His requirements in this direction are, however, rather specialized, the prime necessity being a method of comparing a large number of selected lines, though the careful testing of a small number of valuable new strains against standard varieties is also of importance.

Now one of the greatest advances made by modern statistics has been to revolutionize field trial technique. Until recently, however, the development of field designs was largely concerned with manurial and other such trials, where a limited number of treatments are applied and where interactions of these treatments are detectable and potentially of interest. Furthermore, when it was shown that multiple interactions are seldom if ever significant, a new technique, that of confounding, became possible. A design involving confounding purposely sacrifices information on less important interactions, in order to make the main comparisons with more precision.

Clearly all field trials must be based on the same principles as these 'treatment' designs; but the latter in themselves are not fully suited to the plant breeder's work. He often requires to work with large numbers of varieties and has no uninteresting 'interaction' comparisons which may be sacrificed by simple confounding. His requirements have, however, recently received special attention, and appropriate lay-outs have been developed. For example, the quasi-factorial designs, involving a somewhat complicated application of confounding, meet the needs of the plant-breeder admirably but are in general of small value to those interested in soil treatment.

Thus it is very appropriate that the Imperial Bureau of Plant Breeding and Genetics should publish a technical communication on the subject of field trials, by an author who has been associated for many years with this branch of statistical work*. The publication is essentially introductory in scope, and the contents have been admirably chosen to fulfil this purpose. The first sections deal with the general principles of yield determination and the measurement of experimental error. Then follow descriptions of the randomized block and Latin square designs, together with details of their numerical analysis. The discussion of the use of the Latin square well illustrates the considerations involved in the choice of a design appropriate to an experiment. Multiple factor experiments are next dealt with and the principles of orthogonality and confounding introduced by a simple example. Finally, the split plot technique, which is especially suited to combined variety and manurial trials, and the quasi-factorial designs are briefly considered. The latter is somewhat complex for introduction into an elementary account, but its inclusion is amply justified by its pre-eminent position among layouts for testing a large number of varieties.

The presentation of the material is adequate, though more open to criticism than is the choice of contents, in that it tends at times to be too technical. For example, the introduction of the terms 'self-conjugate' and 'transformation set' into the section on Latin squares is unnecessary as their meanings are not explained, the reader being referred elsewhere for an account of their use. Thus they do not materially aid the argument and are somewhat terrifying to the beginner. The discussion of the *t* test in the third section could also be made much more real for the biologist by the use of actual experimental data as illustrative matter, rather than the very artificial example of two varieties with unequal means but exactly equal variances, which is in fact used.

There can, however, be no doubt that plant breeders will find this publication a helpful introduction to the subject of field trials. Nor will its use end there, as the list of more advanced works given, together with short notes on their contents, in the last section, will serve as a guide for later reading and reference. K. Mather.

NATURE, Vol. 2, June 16, 1870

Scientific Education of Women

"The feature which will probably most clearly mark the year 1869 in the view of the future historian of Education, will be the definite recognition of the rights of women to all the advantages of education accorded to men." This is the opening sentence of an article surveying the position. Reference is made to courses of lectures on physiography, physics and botany given by Huxley, Guthrie and Oliver at South Kensington, and to other courses in London, at Edinburgh, Manchester and Liverpool. The results of examinations based on these courses show that "not only can women compete with men in the qualities essential for severe and successful study, but that in many respects their average attainments are higher than among the working members of a University". The work of the Edinburgh Association, all the teachers of which are professors of the University of Edinburgh, is thought to derive much benefit from its connexion with the University.

As regards medical education, the exclusion of women is considered to be due to the fact that "the teachers and practisers of medicine and surgery form a guild, a professional trades' union, protected and licensed by the Government", who are acting in self-defence.

Circumlocution

A provincial druggist [in France] desirous of gathering fox-glove (*Digitalis*) in one of the State forests, applied for permission to the local authority (*garde général local*), offering at the same time to pay an annual sum of six francs for the privilege. The local magnate transmitted the request to his inspector, who forwarded it to the Conservator of the department, who dispatched it to Paris to the Director-General of Forests, who caused it to be sent to the Minister of Finance. The Minister referred to "for study" to the Director-General of Domains, who sent it to the Departmental Director of Domains to be examined by the Registrar. The latter, after examination, pronounced a favourable opinion on the request, and sent it back to the Departmental Director, who forwarded it to the General Director, who, in his turn, dispatched it to the Minister, through the agency of the General Secretary of Finance, who availed himself of the opportunity to make his comments on the matter. Then the unhappy druggist's request was returned to the Director-General of Forests, who sent it to the Conservator, he to the inspector, and the inspector to the *garde général*, who was the original recipient of the request. The authority "to cull simples", at length reached the successor of the original postulant, and at an age when he was too old to herborize.

Well-wishers of the University of Oxford will rejoice to hear that the honorary degree of D.C.L. has been offered to Mr. Darwin. The state of Mr. Darwin's health unfortunately precludes him from accepting the proffered honour, but the scientific naturalists of this and other countries will not the less appreciate the compliment which has been paid to their great leader. It is all the more graceful as Mr. Darwin is not an Oxford, but a Cambridge man, a circumstance which the University of Cambridge seems to have forgotten.

FORTHCOMING EVENTS

[*Meeting marked with an asterisk is open to the public.*]

Tuesday, June 18

Austrian Academy in Great Britain, at 5 p.m.—Prof. Dr. F. A. Hayek: "The Austrian School of Economics".

Thursday, June 20

Chadwick Lecture (at the Chelsea Physic Garden, Swan Walk, S.W.3), at 4 p.m.—Prof. William Brown, F.R.S.: "Plant Disease in Relation to the Public".*

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Graduate Mistress to teach Mathematics in the English High School for Girls, Istanbul—The British Council, 3 Hanover Street, W.1 (quoting 'Istanbul') (June 17).

Assistant Education Officer—The Chief Education Officer, County Hall, Kingston-upon-Thames (June 19).

Organizer of Agricultural Education for the County of Suffolk—The Secretary, County Education Committee, Education Office, County Hall, Ipswich (June 21).

General Manager of the Rivers Department—The Town Clerk, Town Hall, Manchester 2 (June 22).

Assistant to teach Engineering Science, Engineering Drawing, etc.—The Registrar, Wimbledon Technical College, Gladstone Road, S.W.19 (June 24).

Graduate Assistant Mistress to teach Mathematics and General Form subjects in the Hong-Kong Education Department—The Secretary (I.P.C./C.A.), Board of Education, Alexandra House, Kingsway, W.C.2 (June 24).

Assistant Lecturer in Naval Architecture—The Registrar, The University, Liverpool (June 24).

Technical Assistant to the Executive Officer—The Executive Officer, Rutland War Agricultural Executive Committee, Catmose, Oakham, Rutland (June 25).

Student-Demonstrator in Botany—The Principal, Royal Holloway College, Englefield Green, Surrey (June 29).

Head of the Department of Horticulture—The Secretary, West of Scotland Agricultural College, 6, Blythswood Square, Glasgow (June 29).

Principal of the proposed Technical Institute at Delhi—The High Commissioner for India, General Department, India House, Aldwych, W.C.2 (quoting Appointment 1/11G) (June 29).

Professor of Chemistry at Raffles College, Singapore—The Secretary, Universities Bureau of the British Empire, 88a Gower Street, W.C.1.

Draughtsmen Grade I (Ref. No. A.506) and Draughtsmen Grade II (Ref. No. A.507) at South Farnborough, and Draughtsmen Grade II (Ref. No. A.508) at Gosport—The Chief Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (quoting appropriate Ref. No.).

INTERNATIONAL DEMOCRATIC UNITY

A DECLARATION of Union offered by the British Government was handed to the French Government by His Majesty's Ambassador on June 16. It is not necessary to reproduce here the complete Declaration, though a few phrases may well be emphasized.

> "The two Governments declare that France and Great Britain shall no longer be two nations but one Franco-British Union. The constitution of the Union will provide for joint organs of defence, foreign, financial, and economic policies. . . . During the war there shall be a single war Cabinet, and all forces of Britain and France, whether on land, sea, or in the air, will be placed under its direction. . . . The Union appeals to the United States to fortify the economic resources of the Allies and to bring her powerful material aid to the common cause."

At the time of writing it is impossible to indicate French reaction to this great and valuable gesture of the British Government, neither is it possible at present to speculate on its implications or results. But men of science might well view with pride this political move as following very closely what has been going on in the world of science over a period of many years. Scientific collaboration has gradually been getting more intimate—a fact which will be apparent from an examination of the pages of the last score or so of volumes of NATURE. But such scientific collaboration was not confined to the democracies. Until comparatively recently, communications to the Editors arrived from all countries where scientific research was being pursued, that is, all civilized countries. It is true that, in the few years preceding this War, communications from the Totalitarian States, especially Germany, had been reduced almost to nil, whereas from the Democratic Powers and smaller Democracies, and especially from the U.S.S.R., there has been a decided increase.

In the Declaration, it is suggested that the "two Parliaments will be formally associated". International scientific parliaments in the form of congresses, conferences, symposia, etc., had already, until the outbreak of war, been more and more frequent and comprehensive.

But by the intensification of totalitarian policy, international scientific policy has been adversely affected. On several occasions international conferences have been postponed or cancelled. This has had the effect of forcing men of science of democratic, free countries into closer collaboration. Contact between British and American men of science has become more intimate during the past two or three years, as exemplified in many ways such as the closer relation between the British and American Associations for the Advancement of Science marked by the inauguration of the British and American Association Lecture in 1938. In present circumstances, we hope that British and American collaboration will not only continue but also become intensified.

Collaboration between the British and French Associations was developing before the outbreak of war; but shortly after the start of hostilities, important moves were made to bring the men of science of these two great democracies into even closer union. We may now disclose the fact that a strong group of French scientific workers were inquiring into the possibility of publishing periodically in NATURE articles contributed by French men of science in the French language—a suggestion which was viewed favourably by the Editors. Whether such a scheme will now prove feasible remains to be seen.

But a comprehensive scheme for collaboration by means of the centralization of scientific knowledge was already developed by a French group in the early stages of the War, and its machinery set working at the beginning of this year. Faced with an output of research papers running into millions, the recording of existing knowledge is a problem as important and difficult as any connected with science. For this reason, a Service de Documentation, under the direction of Prof. Pierre Auger, was established by the French Government's Centre National de la Recherche Scientifique.

The Service de Documentation has begun the issue of a *Bulletin Analytique**, which contains the titles or very short abstracts of papers published in the chief journals of chemistry, physics, applied chemistry, technical physics, biochemistry, and some branches of biology (see also p. 965). It is hoped to publish the *Bulletin* in fortnightly parts, with quickness of publication as a particular aim, and to publish every abstract within a month of its preparation. This speed is obtained by brevity and good organization. The *Bulletin Analytique* is intended mainly to aid the specialist.

The Service has also organized an archive of original papers. It also offers to file a copy of any typescript paper acceptable to it, and include an abstract in the *Bulletin.* Such abstracts are given a special mark. Copies of the deposited typescript can be made by machine, and supplied to applicants.

Extensive use is to be made of microfilms. Negatives will be made of any paper abstracted in the *Bulletin,* and positives supplied to research workers in laboratories and institutes. The cost of these positives is astonishingly low. A strip of film bearing images of ten pages of a paper costs about one penny. Films of very long papers and typescripts containing large numbers of illustrations cost a few pence. The images on the film are 18 mm. × 24 mm. in size, and when magnified ten times make a page of normal size. The images of the pages may be read through a small eyepiece costing about 7*s.* 6*d.*, or they may be projected in page size on to a horizontal screen by a simple projector which costs less than £3. A third instrument at an intermediate price has also been devised.

Bibliographies of special subjects are made by assembling sections of microfilm. The sections are 19 cm. long and contain images of ten pages. They are placed in a file 20 cm. in size. One file will hold a substantial bibliography, and a drawer of files can contain microfilms of thousands of original papers.

The head office of the Service was established in the rue Pierre Curie, Paris, but we trust that arrangements have been made for it to function elsewhere now that Paris is in enemy hands. Some of the chief members of the staff have been associated with the "Tables Annuelles", and they are assisted by about forty abstractors and translators. Besides preparing the *Bulletin* and supplying microfilms of desired papers, the staff undertake on request the preparation of indexes and dossiers on particular subjects. They also prepare translations of papers in the less widely known languages.

The Service is at present limited to France, Great Britain and their Dominions and Colonies. It has already received valuable aid from the Science Library in London. This is the type of collaboration between British and French institutions which should be extended and, above all, made permanent and extended to those of other countries.

One of the most interesting features of the Service is that it has been organized by an experimental physicist. It provides evidence of the administrative ability dormant among young men of science. The scientific worker has the great advantage as an administrator in his own field of knowing exactly what he is dealing with, and what he wants, and he can accordingly devise the most efficient organization for providing it. The non-scientific administrator, with the utmost good will, frequently fails to grasp the possibilities in scientific matters, and does not understand how to create the conditions in which science can be used most effectively.

The establishment of the Service de Documentation for the aid of scientific workers both in France and Great Britain emphasizes once more the need for improving communications between democratic countries, so that the best co-operative use can be made of their national institutions.

It is not possible at the time of writing to get in touch with Prof. Auger, and therefore we cannot know the present plight of this Service, which augured so well for the contribution of science to international democratic unity. Much less is it possible to foretell the immediate future of British and French scientific collaboration; though of the ultimate future there can be no doubt.

---

CAMOUFLAGE IN MODERN WARFARE

AT times like the present, when the threat of aerial bombardment and the possibility of invasion broods over Great Britain, public interest is naturally aroused in the subject of camouflage and its role in modern warfare. In happier and more normal times camouflage has been of interest primarily to the naturalist, who sees in the coloration of different wild animals a variety of devices which render them extraordinarily difficult to detect in the field. The underlying optical principles which govern visual concealment and deception are biological principles, the discovery and description of which are mainly due to the observations of naturalists and sportsmen. These men, whose labour or leisure has brought them into intimate contact with wild creatures, claim no particular credit for their discoveries, which are essentially an exposition of principles beautifully demonstrated by Nature herself.

The general application of these principles for war purposes was first suggested to a Government Department by Prof. (now Sir John) Graham Kerr, who in September 1914 communicated to the First Lord of the Admiralty methods of rendering ships at sea less easily recognized—in particular, by means of countershading, and disruptive coloration or 'dazzle' as it was called later. More recently the problem of camouflage has been intensely studied by Dr. Hugh B. Cott, whose lecture to officers at Chatham (*Royal Engineers Journal*; Dec., 1938) summarized a subject which he has dealt with more fully in an important work on "Adaptive Coloration in Animals" just published*. Well-defined principles of camouflage, derived from research in biology and psychology, are now established ; but authorities in the various Service Departments concerned have been slow to make the most of this available knowledge. Indeed, the history of war camouflage provides an extraordinarily convincing example of the ineptitude of the existing system where science is concerned.

In reply to a question by Mr. S. F. Markham, Sir John Anderson stated in the House of Commons on August 2, 1939, that he did not propose, "as at present advised", to attach a biologist to the Camouflage Research Station. He had, however, invited a biologist to serve on an Advisory Committee to which he proposed to refer questions of scientific principle affecting camouflage. After an interval of eleven weeks from its constitution, this Committee was summoned to meet for the first time on October 18, 1939. During its subsequent brief history, the scientific experts serving on this panel were kept to a great extent in ignorance of the camouflage policy and programme operating in the Service Departments ; co-operation between the different departments and even within individual departments was lacking ; insufficient attention was paid to research and to the advice of members of the panel ; and there was evidence of slackness and lack of initiative and interest by officials concerned on the executive side. Before the end of March of this year, the chairman, and the two members of the committee possessing the requisite scientific and practical qualifications, had resigned or expressed their desire to resign.

On April 18 last, the Secretary of State for the Home Department announced that after examining the question of camouflage in the light of the experience gained since the beginning of the War, he proposed some reconstruction of the present organization of this work in reference to war needs. In due course the advisory committee, now termed the Camouflage Committee, was reconstituted under a new chairman, so as to include, among others, responsible representatives of those branches of the three Service Departments and the Ministry of Supply which are concerned with camouflage work. It was hoped that these changes would result in greater co-ordination and more effective pooling of information. Such hopes have, however, proved groundless : we are informed that the Camouflage Committee has not yet held its first meeting.

An illuminating commentary upon the lack of progress—remarkable even for a Government Department in these stirring times—and upon the failure to make proper use of those best qualified to serve in this field, is provided by a question and reply given in the House of Commons so recently as June 5 last, when Sir John Graham Kerr asked the Home Secretary whether he was aware that the establishment of the scientific principles which determine the effectiveness of camouflage was the work of biological specialists in this subject ; that one of the leading authorities in this specialized branch of science was a British subject; and whether steps had been or would be taken to ensure that his full-time services should be available to the country during the present emergency. The following reply was made by Sir John Anderson:

---

* Adaptive Coloration in Animals. By Dr. Hugh B. Cott. Pp. xxxii+508+49 plates. (London: Methuen and Co., Ltd., 1940.) 40*s*. net.

"I am aware that biological science has made an important contribution to the study of camouflage, and I have invited a British biologist to serve on the Camouflage Committee. He has accepted my invitation and will, I have no doubt, be ready to give to the matter as much of his time as may be required."

We believe that the Committee concerned has never met, so it would scarcely appear that the best possible use is being made of this biologist's knowledge and experience.

When we turn to the personnel engaged at the Civil Defence Camouflage Establishment, the prospect is scarcely reassuring. Of some sixty-five technical officers, all but four are either professional artists or, at the time of recruitment, were students at art schools. Not one member of the establishment is a qualified biologist. It appears, moreover, that none has attended a course in the science of camouflage, and indeed at the present time there does not exist any such course of instruction which they could attend.

When the fact is realized that camouflage research and application are at the present time largely dominated by artists, or in the hands of Civil Servants and Army officers, and in either case controlled by people lacking the necessary scientific training and with no knowledge of the fundamental biological and psychological principles involved, the failure to achieve effectiveness which one sees on every side is rather to be expected than wondered at. But it is not less deplorable on that account.

The general lack of appreciation of the scientific background of camouflage has led to the neglect, or misapplication, of such basic principles as countershading, disruption, coincident pattern and deflection. As a result, much contemporary effort at camouflage has failed utterly and is consistently failing to attain effectiveness.

A serious fallacy—though one which need cause little surprise when we remember the artistic qualifications of those concerned—is seen in the excessive reliance placed upon paint, as opposed to structural camouflage. Only rarely is pigment able to counteract the effects of light and shade, and of cast shadow, presented by vehicles, buildings and other solid bodies in the open. Still less is paint of value when it is put on, as it is being put on everywhere at present, in defiance of the well-established scientific principles of countershading and disruption.

An efficient way of rendering a solid object easily recognizable is to paint it all one colour. Continuity of surface, unbroken outline, and relief will then reveal to the eye its true nature without the interference of illusion or distraction. Now the type of camouflage seen, for example, on Service vehicles displays a ludicrous attempt at disruption which fails entirely since the colours used are of approximately equal tone. Mere differences in tint become invisible at a short range, and objects so coloured are virtually self-coloured and hence self-evident.

Another common misapplication of paint, again unfortunately understandable in an artist used to thinking in terms of pictorial representation, is seen in the attempt to camouflage large structures such as hangars with representations of trees done in paint. An extravagant example of this foolishness was the decoration of the cooling towers of a large works to represent a grove of tall trees. It should scarcely be necessary to point out that the result of light and shade is such as absolutely to kill this piece of stage scenery at bombing range. Such exhibitions are the more to be regretted since they tend to bring down ridicule upon the art of scientific camouflage.

The principle of countershading, whereby the appearance of relief (upon which the visual interpretation of form and solidity so largely depends) is obliterated, has an obvious application to all kinds of objects of importance in war—tanks, torpedo-tubes, guns, aircraft, and buildings. Indeed, in principle, all camouflage by mere paint should be worked out on a basis of countershading. But Thayer's principle is still ignored by the authorities in the Service Departments. Even the simplest case, that of a gun, has been consistently bungled, frequently by being divided into an upper dark and a lower light half, without any attempt at gradation between the two, a method which shows that the basic principle of obliterative shading has never been grasped by the authorities concerned. A glaring example of incompetence was a recent photograph in the daily Press showing a coastal defence gun painted in a manner which nullifies Thayer's principle. The same remark applies to the vast majority of 'camouflaged' Service vehicles on the roads to-day.

A hard case of official ignorance is presented by the use of cryptic paint on bus-tops. The roofs of many double-decked buses now have been treated with grey or green and brown ; but the front, back and sides—the parts most visible in oblique view from the air—are coloured a brilliant red—the very hue the chief attribute of which is its carrying power and conspicuousness. Similarly many buildings have the roof camouflaged and the side walls neglected.

When we turn to camouflage at sea, we find that by a reversal of evolution, disruption (or 'dazzle'), used with success towards the end of the War of 1914-18, has now been abandoned ; and abandoned because of its supposed unsuitability in view of the fact that ships are seen against constantly changing backgrounds of sea and sky. It is scarcely necessary to mention here that this fact is, of course, the very reason why disruption, rather than self-coloration as at present, should be used as the only effective way of hindering recognition at sea.

So long as the present unsatisfactory state of affairs lasts, injury will continue to be done to the nation's war effort. The matter is urgent. Camouflage is destined to play a great part in the struggle. To those who have only given the matter hasty thought, the problem of visual concealment may appear in a minor role. Biologists and others who fully realize its scope and possibilities take a very different view ; and among those who know most there is a growing sense of uneasiness. At no time in our history has camouflage been of such vital importance as it is to-day. Yet under the present system, the men who know best what should be done seem to be excluded from getting anything done. Unless, and until, the fundamental biological principles are understood and applied by the authorities, attempts at camouflage are merely ridiculous. Now, after all these months of muddling and waste, and at this eleventh hour, the Government Departments concerned—Navy, Army, Air and Civil—must be urged in the strongest possible manner to take up the question of camouflage seriously and to tackle it scientifically.

PROF. FRANZ BOAS

Race, Language and Culture

By Franz Boas. Pp. xx+647. (New York: The Macmillan Company, 1940.) 21*s.* net.

IN this volume Prof. Franz Boas, the doyen of anthropologists of the United States, has reprinted a selection of his briefer but not, therefore, less weighty contributions to anthropology in the course of his long career. The earliest is dated 1887, and deals characteristically with the methods and subject-matter of geography, more especially in its humanistic aspect. The essays are classified, as the title indicates, under three heads ; and the order is logical rather than chronological. This order is the more appropriate in that while naturally as knowledge and experience have grown they have brought with them clearer insight into the processes and possibilities of the science, yet from the very beginning Prof. Boas has been singularly consistent in his methods of approach to certain aspects of the study of man.

Throughout his career, but more especially in his later work, Prof. Boas has held fast to the conception, not so common in his earlier days, that the results of anthropological investigation are not merely concerned with the backward and primitive, but are applicable to the needs and problems of modern civilized communities. Hence in dealing, for example, with problems of race, he is not content to examine and analyse physical measurements as the sole basis of investigation, though allotting them their due share of significance, but envisages the sum total of the conditions, environment, psychological, social and the like, bearing upon the problem under consideration. In this respect he stands alone, without rival.

In this collection of reprinted pieces, representative examples will be found of much of the most original and lasting contribution by Prof. Boas to anthropological thought in general and the anthropology of the American continent. Here is his report on studies in the changes in bodily form of the descendants of immigrants, which has been the source of much controversy, as well as "Race and Progress", the presidential address to the American Association for the Advancement of Science in 1931, in which he challenged Sir Arthur Keith's dictum that racial antipathy was implanted in man by Nature in the interests of natural selection. In view of the causes underlying the present European conflict, and the population problems of the American continent, these studies are of both topical and abiding interest.

In the section dealing with cultural subjects are several papers which touch upon the culture of the Kwakiutl and other peoples of the North-West Coast. Prof. Boas has long been devoted to the study of this region, which has bulked large in the development of the American historical school of anthropologists, of which he is rightly regarded as the founder. In addition, he has also included some of his important contributions to the study of development of primitive art, which at the time of their first publication in 1903 and 1908 were little short of revolutionary in their effect upon the approach to the study of conventional design.

THE PRINCIPLES OF DEVELOPMENT

(1) Principles of Development

A Text in Experimental Embryology. By Paul Weiss. Pp. xx + 601. (New York: Henry Holt and Co., 1939.) 5 dollars.

(2) Les progrès récents de l'embryologie expérimentale

Par Prof. Maurice Caullery. (Bibliothèque de philosophie scientifique.) Pp. 236. (Paris: Ernest Flammarion, 1939.) 22 francs.

(1) PAUL WEISS'S "Principles of Development" is one of the most complete accounts of experimental morphogenesis to appear in recent years, and certainly deserves a welcome in a field not too well provided with general texts. It attempts to combine a text-book with a critical discussion of the theoretical principles on which our interpretation of developmental phenomena is based. The hybrid is a vigorous animal and will give any reader a good run for his money, in spite of the fact that while its main body is galloping rapidly forwards its intelligence is hampered by a nostalgia for yesterday's metaphysics.

As a text-book it contains several brilliant innovations. The introductory inventory of development, with its discussion of growth and of the gradual differentiation of cell-strains; the discussion of the methodology of embryological research; and the account of the development of the nervous system and behaviour, with its implicit admission that development is one of the dimensions of all biological phenomena, characterizing physiological functioning just as much as anatomical structure; all these sections are exceedingly well done. It is only in the middle section, where the emphasis is dictated by the type of analysis adopted, that doubts arise.

Even in this part it is only rarely that the theoretical weaknesses have led to actual mistakes, although one must regret the uncritical acceptance of the isolation experiments on the chick as providing evidence about the properties of the germ as a whole rather than of the organizer; nor is there any justification for omitting any reference to the existence, let alone the functions, of the endoderm. The important criticism is that Weiss seems to mistrust most of the analytical concepts to which causal significance can be attached. This is most obvious in the case of genes, which are dismissed with a footnote reference to text-books of genetics. But in the discussion of the organizer, which is at present the central principle of developmental mechanics, although Weiss follows the English school in making a distinction between the properties of producing an inducing stimulus and of controlling the arrangement of the resulting tissues, he is unwilling to pursue this line of thought beyond the comparatively superficial aspects of the phenomena. Thus he deals most inadequately with the connexion between morphogenesis and metabolism, and in this way underemphasizes a line of work which is being actively pursued by biochemists at the present day, and is perhaps the most likely to bring developmental phenomena into closer relations with the rest of experimental biology. On the other hand, the book contains a fine discussion of one of the other promising lines of causal analysis, namely the influence of fine-structures at the liquid crystal level. This is a field in which Weiss has himself made some of the most notable contributions, and his evaluation of it is excellent.

Weiss formulates development largely in 'field' terms; a process such as the formation of the neural plate is for him a resultant of "field pattern" and "field energy". He gives an admirable analysis of the field concept, for the introduction of which into embryology he was largely responsible. In this analysis he makes it quite clear that the field is a descriptive convenience, not a causal agent. But can one then be content to formulate an experimental science in purely descriptive terms?

(2) Prof. Caullery's little book is a straightforward account of recent work in experimental embryology. There is no need to discuss its theoretical basis, since it does not attempt to penetrate beneath the

generally accepted ideas. It provides a short, clear and remarkably complete summary of the newer developments, and is, an agreeable surprise in a French book, adequately illustrated, though it still suffers from the poverty of index which is another unfortunate national characteristic. If available, it should have a wide sale in Great Britain, since it is both cheaper than any other comparable text-book, and also provides the student with the essential information in a much shorter space than any of its competitors.

C. H. WADDINGTON.

REGIONAL GEOLOGY OF THE EARTH

Regionale Geologie der Erde
Herausgegeben von K. Andrée, H. A. Brouwer und W. H. Bucher. Band 2: Palæozoische Tafeln und Gebirge. Abschnitt 2: Northwestern Europe Caledonides. By Prof. E. B. Bailey and Prof. Dr. O. Holtedahl. Pp. 84 + 2 plates. 14 gold marks. Abschnitt 3: Mittel- und Westeuropa. Von Prof. Dr. Hans Becker. Pp. 114. 14 gold marks. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1938.)

IN this new "Regional Geology of the Earth", of which two parts are noticed here, there is to be presented a summary of the geological history of the earth's surface in which emphasis is placed more on tectonic and magmatic events than on details of stratigraphy. The division into regions for description is based upon tectonic history but, at the cost of some overlapping, complete geological accounts are to be given of each region. The work is intended for the trained geologist, and attention is therefore to be directed as much to unsolved problems as to criticism of materials already assembled.

The complete work is projected to consist of three volumes, the first dealing with the Ancient Coigns, the second with the Palæozoic Plateaulands and Folded Belts, the third with the Later Orogenic Belts. The two parts considered here belong to volume 2, and are concerned respectively with the Caledonian and Variscan mountain-building in Western Europe.

(1) The first part provides a summary of the geological history of the Caledonian fringe of north-west Europe. It deals with the margins, contents and fate of the Lower Palæozoic geosyncline which stretched from Spitsbergen through Norway into the British Isles. Prof. O. Holtedahl is responsible for the sections dealing with the Spitsbergen and Scandinavian portion of the geosyncline, and Dr. Bailey for the British portion.

For British readers, Holtedahl's account of a modern Scandinavian view is of particular importance. He supplies two plates of great value. The first of these is a correlation of the sedimentary series belonging to the Caledonian cycle in the Arctic and Scandinavia, the second a geological map of the Scandinavian Caledonian zone on a scale of about 1 in 250,000. Amongst a multitude of interesting topics, two may be cited, namely, the importance of Eocambrian (Sparagmite) in the Caledonian zone, and the genetic connexion between high-grade metamorphism and Caledonian igneous activity.

Bailey's treatment of the British Isles is a marvel of compression, as it provides within some 30 pages a summary of British geological history from Lewisian to Pleistocene. This summary is embellished with excellent, if schematic, maps of Scotland, Ireland and North England and Wales. In so short an account it is necessary for the author to take sides in many controversial questions, but this is done fairly, especially in connexion with differences of opinion on Highland problems. Holtedahl's views on the importance of the sparagmite in Norway and on the Caledonian age of the metamorphism there are echoed by Bailey for Scotland, in that he suggests that the Dalradian may be sparagmite, and the Highland metamorphism Ordovician in age. These suggestions will be of great interest to Scottish geologists, who will doubtless reflect upon them.

References to literature are merely skeletal and there is no index—perhaps this latter is not needed for a 75-page account.

(2) Prof. Hans Becker deals with the Variscan and Saxon tectonics of Western Europe. He gives a summary of the pre-Variscan elements, the Variscan folds, Palæozoic magmatic history and the folding of Saxon style, and carries the geological history up to the present day. Whether one admits or not the justification of so compressed a summary as Becker gives, one is nevertheless rewarded by the last half-dozen pages of this part. Here brief mention is made of a series of interesting topics—the Variscan magmatic cycle, the meagreness of the Variscan geosyncline, the consequences of this and the source of the geosynclinal fill, some general criticism of the geosynclinal-orogenic doctrine, peculiarities of the movements of Saxon style, and so forth. One could wish that these topics had been made texts for the whole sermon.

THERMODYNAMICS AND THE LOWEST TEMPERATURES*

By Dr. C. G. Darwin, F.R.S.,
Director, National Physical Laboratory

Equipartition of Energy

THE subject of thermodynamics goes, of course, beyond the familiar principles of ordinary dynamics, and it is therefore natural that we must have an extra principle in order to be able to work it. This principle which I am going to use is the *equipartition of energy*. Suppose that we have a closed vessel containing a gas, say, oxygen. If we imagine that we knew the motion of all the molecules at some instant of time we could work out their kinetic energies, and adding them together we should have the total energy of the gas in the vessel; a perfect gas has no potential energy, and oxygen is nearly perfect. We could divide this total by the total number of molecules, and so get the average energy of a molecule. Moreover, since the collisions do not change the energy, the average will be constant as the time goes on. Now suppose that we take two gases together, mixing, say, hydrogen with the oxygen. The atoms of the two kinds can now collide with one another and interchange energy, and the question arises of what happens. The theorem of the equipartition of energy tells us the answer. It asserts that the average energy of a hydrogen molecule will be equal to that of an oxygen, and this no matter what the proportions of the two gases that may be mixed together. Since energy is proportional to the square of speed, and the oxygen molecule is sixteen times as heavy as the hydrogen, it follows that the hydrogen molecules are on the average moving four times as fast as the oxygen.

This is the simplest example of the theorem, simplest because we have taken perfect gases. But it is true in other cases, so that any part of any system that is capable of exchanging energy will take a share of the energy, and on the average will have exactly the same amount of kinetic energy as the molecule of the gas. Now when a number of things are intimately mixed together they are thereby compelled to come to the same temperature. We identify the average energy of equipartition with the temperature, and it may be shown that in fact it is identical with the temperature measured on Kelvin's absolute scale. The average energy of an atom of a monatomic gas is $\frac{3}{2} kT$, where k is a known very small constant. Here is a link with pure thermodynamics, but it is still an incomplete one, since thermodynamics makes great play with a second quantity, entropy. For a full consideration of statistical mechanics it is, of course, indispensable to fit entropy into the scheme, but for my present purposes I can do without it.

I have enunciated the theorem in its simplest case and have oversimplified it in so doing. In the first place, I said nothing about the rotations of the molecules, which will also share in the equipartition. Thus a monatomic gas takes three shares per molecule, each of $\frac{1}{2} kT$, one for each dimension of space, whereas a diatomic takes five, since it can turn about two directions in space. More complicated molecules may have six shares, but for most of them other effects enter which I shall not discuss. Each atom of a solid usually has six units, three for the components of kinetic energy and three for potential energy. But there is a much more important modification which must be described.

The rule of equipartition implies the celebrated law of Dulong and Petit, that the specific heats of equal numbers of atoms of different substances should be the same. This law holds for most substances, but long ago certain puzzling exceptions were known; for example, the diamond has a much smaller specific heat than it should have. Moreover, the law implies that just as much energy should be taken to raise a body from 1° K. to 2° K., as it does from the freezing point 273° K. to 274° K., whereas it was found at the end of last century that at these deep temperatures the specific heats of all substances become very small—the diamond only differs from the rest in that its specific heat has started dropping earlier. This mysterious fact was later fully explained by means of the quantum theory, and arises from the rule that energy cannot be taken up by the atoms in arbitrary amounts but only in definite units. The way the process works may be described by a metaphor. Imagine that we have a large town, the health of which is cared for by a number of medical men. The rich men's doctors charge large fees and get few patients, while the poor ones get many small fees. I shall suppose that no doctor is allowed to change the scale of his fees. Then, when the town is prosperous, on the whole the doctors may all earn about the same money. This is the state of equipartition. But now suppose that the town is hit by an economic depression. Everyone suffers, the doctors included, but not equally, for no one will have the money for a large fee, and so whereas all the doctors will be poorer than before, the Harley Street doctors, who are not allowed to lower their fees, will be put right out of business. Consequently the total income of the medical profession is diminished out of proportion to that of the rest of the community.

---

* From the Kelvin Lecture delivered before the Institution of Electrical Engineers on April 25.

This is a metaphorical description of what happens at deep temperatures. The matter is made a little harder to appreciate because it is not the separate atoms that constitute the units on which the energy is placed; it is combinations of them in the form of elastic waves of vibration. The shorter waves that require large doses of energy are frozen out and get none, and the only ones that get energy are the longer ones, which can accept it in small quantities. It is this effect that causes the specific heat to be much less at low temperatures.

PARAMAGNETIC REFRIGERATION

The first stages in the history of refrigeration were carried out by a variety of processes connected with the condensation of vapours. By such means all the permanent gases have been condensed, but at about 1° K. the potentialities of the method are exhausted. To go further a new method is called for, and this has been found by making use of magnetism. We must therefore briefly consider the theory of magnetism.

As is well known, materials may display any one of three different magnetic characters. The majority are diamagnetic. These are weakly repelled from a magnet, and their nature arises from an undamped eddy current induced in each atom as the field is put on and annihilated again when it is cut off. Diamagnetism is a phenomenon of each separate atom or molecule, and is independent of the temperature. Then there is ferromagnetism, the ordinary magnetism of iron and nickel. This is an enormously strong effect by comparison, and its theory is moderately well understood: it has interesting thermodynamical features, but they are mostly at high temperatures. The third effect is paramagnetism. In this the body is attracted by a magnet, as in ferromagnetism, but about a million times less, so that the weak attractive force is of about the strength of the repulsive diamagnetic force, or perhaps rather more. The enormous quantitative difference between para- and ferro-magnetism is due to a qualitative difference, for in paramagnetism it is the separate atoms that are responsible, whereas for ferromagnetism it is certain very intense interactions of the electrons in the atoms. Paramagnetic susceptibility is very much affected by temperature, and it is this that makes it of interest here.

Think of each atom as containing a little freely suspended bar magnet. These magnets possess energy and can rotate, and there are interactions between the rotations and the other heat movements of the atoms of the specimen. Therefore there is equipartition between them, and at ordinary temperatures we have to think of the little magnets mostly whirling round rather fast. On account of this whirling they point on the average equally in all directions and the specimen is unmagnetic. But now put it in a magnetic field. We are not concerned with the diamagnetic effect, though it will be present, but there is a second more important effect to consider. Each magnet will now no longer rotate uniformly, but will move like a flywheel a little out of balance. Some go fast, some can barely get over the dead centre, and some may happen to have so little energy that they oscillate instead of rotating. The outcome of this is that when an average is taken, the magnets tend to point slightly down the field, and thus the specimen acquires a slight magnetic moment, which agrees in direction with that of the field, and is usually strong enough to swamp the diamagnetic moment in the opposite direction. The paramagnetic moment, depending as it does on the energy of equipartition, will vary with temperature and is found to be inversely proportional to it, so that at low temperatures paramagnetics have greatly increased susceptibilities. If we could get down to the absolute zero, all the magnets would be at rest pointing down the field, and the specimen would be saturated, so that no increase of external field could increase its magnetization further. Effects of saturation are observed for some substances at the deepest temperatures, but I do not need to consider them here. It is sufficient to note that the magnetization in a given field will go up as the temperature goes down, since this suggests a method by which conversely we can alter the temperature.

The process was first proposed by Debye and independently by Giauque, and before explaining why it works we will see how the experiment is done. The first work was done with gadolinium sulphate for the reason that its paramagnetic behaviour is exceptionally well understood, but of late commoner substances, such as iron alum, have been more used. A specimen, usually in the form of a powder, is first cooled down with liquid helium. It is next placed in a strong magnetic field, as a consequence of which it begins to heat up again, but this heat is also absorbed by the liquid helium. The helium is next removed, so as to insulate the specimen, and then the magnetic field is cut off, and as a consequence the temperature drops immediately to a very low value. Technically the process is, of course, very difficult, but this drop in a single step to the lowest temperature is in some ways very much simpler than the elaborate sequence of pumping and repumping of vapours that has to be done in the earlier stages of the refrigeration.

We must now try to understand why the process works. As it is a magnetic process, it will depend on somehow getting energy out of the little magnets. A magnet placed in a magnetic field oscillates with a certain frequency, and if the field is weakened the frequency diminishes so that it oscillates more slowly. That is easy, but it is by no means so easy to see what happens to the *amplitude* of the oscillation as the field changes. It is easier to see this by taking the analogy of a pendulum so arranged that its frequency can be gradually altered. To do this we tie a bob *W* to a long string and make the other end fast at *A*. The string passes through a hole *B* in a light frame, and the frame can be slid up and down a groove vertically below *A*. It is thus only the part *BW* that swings. If *B* is low the pendulum is short and swings with a high frequency, but if *B* is up near *A* the swing is slow. What happens when we give the bob a measured amplitude of swing with *B* at the top and then slowly lower *B*? The reaction on the frame at *B* is half the time to the right and half to the left, but whether the bob is to the right or the left the reaction is always slightly upwards, only ceasing to be so at the instants when the bob is vertically below *A*. If then *B* is slowly lowered, it is lowered against a force, and so does work, and the bob therefore acquires energy. Conversely, if it is raised, the frame absorbs work and the bob loses energy. The solution in detail shows that at every stage the energy of the pendulum is proportional to the frequency. The result is general; when a vibrating system has its frequency of vibration raised it acquires energy from outside, when slowed down it loses energy.

Applying this to our magnets, think of one of them which is doing a small oscillation in a weak magnetic field. If the field is increased the frequency of oscillation will increase, and therefore the energy of the magnet will also increase, the work for it being done by the external field. Conversely, if we start in a strong field and slowly weaken it, the magnet's energy will decrease. Thus when our paramagnetic is put into the strong field the little magnets get more energy than is justified by equipartition and this they share out, so that the specimen heats up. This heat is absorbed by the liquid helium, and the magnets are left with the equipartition energy of the liquid helium. When the field is weakened, the magnets lose most of their energy and so will have very much less than the equipartition amount. They try to restore equipartition by borrowing energy from the other parts of the system, and so the temperature is lowered.

The process works at any temperature for a paramagnetic, but is very feeble at room temperatures. It becomes effective at deep temperatures for two reasons. First, the magnetic susceptibility becomes much bigger, so that attainable magnetic fields become much more efficient, and secondly the specific heat becomes much smaller, so that a given extraction of energy changes the temperature much more. In this way it comes about that it only takes a single stage to lower temperature from about 2° K. to about 0·003° K.

Before passing on to the properties at these new temperatures, I ought to confess that in one respect I have rather simplified the statement. An atom is not so much like a bar magnet as like an electromagnet. We may liken it to a perfectly conducting ring carrying current. As the field changes, the plane of the ring changes too, and the same things happen to the energy as I have described, but they are rather more complicated because one has to consider a motion something like that of a top, and this is more troublesome to think about than that of a pendulum. I might also add that though the way I have used of watching the energy gives one an easier insight into the process, in most cases it is quite troublesome to apply, and the orthodox thermodynamic use of entropy is far simpler.

There have been several schools of workers in this field. Giauque in America was the first to apply it, and he has made a detailed study of the properties of matter round about 0·1° K. In such work as this, mere record breaking is not the main thing, and Giauque's work has been as useful as anyone's, even though others have gone much further. De Haas of Leyden has got down to about 0·003° K., and Simon of Oxford to about the same. In addition to getting to such temperatures, we want to know what they are on the absolute scale, and this calls for more elaborate work. Anyone who has studied the thermodynamics of ordinary temperatures will remember what a troublesome business it was to fix the scale by such methods as that of the Thomson-Joule experiment. As a matter of fact, the new problem has turned out to be rather easier, because heat losses at these low temperatures can be made very small, so that the system can be approximated much more easily to the ideal thermodynamic engine of Carnot, and hence the temperature can be measured directly. Even so, it is not easy work, and the lowest temperatures attained are still rather conjectural. Pre-eminent on this side of the problem has been the work of Simon and his collaborators, who have fixed the absolute temperature scale with considerable accuracy down to 0·01° K.

The properties of matter at these temperatures are interesting. First, there is to all intents no vapour left at all; it is this that makes the heat insulation so good. Then the specific heat becomes very nearly simply that of the magnets, since the other parts have so little that they scarcely count. But there are technically much more interesting features. In my description of paramagnetism I spoke of each little magnet as simply exposed to a controllable external magnetic field, but in fact it is of course also in the field of all the other little magnets. As the temperature drops, they all begin to line up and cumulatively to exert forces on one another. Each little magnet cannot be expected to know where the force on it comes from, but will react to the total field acting on it. The result is important, and was until very recently most puzzling. The old theory of these local fields was that of Lorentz, and for long it had been accepted without question. According to this theory the susceptibility should be inversely proportional not exactly to T but to $T-\theta$, where θ is a calculable temperature which for most things should be in the region of 1° K. Below this temperature the substance ought to be capable of becoming a permanent magnet; in the old days the question had only an academic interest, but with the opening up of this new range of temperatures it was interesting to see whether it would. The experiments failed to find any permanent magnetism at the predicted temperature θ, but there is a faint and rather doubtful suggestion of it at a good deal lower temperature.

This subject is much more exciting than might appear at first sight, because a similar theory was applied for electricity as well as for magnetism, and there it led to such fantastic results that for long no one was willing to face the problem at all. Just as magnetic permeability is largely due to little magnets tending to point along the magnetic field, so the dielectric constant of a non-conductor is largely due to electric dipoles twisting round under the external electric force. In particular, the large dielectric constant of water is mostly due to the strong electric moment of the two H's that lie in directions roughly at right angles from the O. Now dielectric polarizabilities are mostly much larger than magnetic susceptibilities—something like ten thousand times as large—the consequence of which is that the critical temperature for them is very much higher. For water this temperature ought to be nearly 1000° C. This is a fantastic result, for it means that if we fill a hose with water and then bring the ends together, the water ought to become violently polarized with one end positively charged and the other negatively; it would be a strong horse-shoe magnet, only electric and not magnetic. Until about four years ago, nobody knew at all why it did not do this, and the theoretical result was so contrary to the facts that anyone who realized the difficulty was frankly terrified of the whole problem. Happily we now know that Lorentz's theory is too simple, and an explanation has been found by various workers which removes the trouble by showing that the co-operation between adjacent magnets, or dipoles, needs more thorough discussion than in Lorentz's theory. No one even now knows the full answer, but it is quite clear that there is no reason to expect the onset of permanent magnetism at the critical temperature, and it is to be conjectured that it will not come at any point above the absolute zero. Reverting to the magnetic case, this same theory applies and it removes the expected trouble, but the whole subject is not even now very clear.

If it is so comparatively easy to get down to 0·003° K., what stops us there? The answer is that for each substance there is a sort of barrier preventing further chilling. One can see that when all the magnets are pointing the same way it would not be possible to get any further chilling anyhow, but some time before this point, thermodynamics shows that there must inevitably be a large increase in the specific heat extending over a certain range of temperature. This rise of specific heat checks the temperature drop, and would make it very hard to get below it. The effect is really a convenience rather than the reverse because, once the specimen has got into the range, its temperature will stay nearly constant for some time in spite of the inevitable leakage of heat into it from the surroundings. The barrier temperature can be lowered by taking a more dilute crystal, for example by mixing the iron alum with some non-magnetic alum, but the process will break down in the same sort of way that occurs in the production of cold by vapours. The diluted crystal will have fewer little magnets available for giving up their energy, and so we should have to take a larger specimen or use a stronger magnet so as to get even the same temperature drop. To get much below 0·003° K. we should therefore have to take a great bulk of inefficient material in a strong magnetic field (and, of course, in a vacuum), and it simply cannot be done technically. The method of demagnetization by means of paramagnetism is exhausted at somewhere a little above a thousandth of a degree.

NUCLEAR REFRIGERATION

This is more or less how matters stand now, but it is not necessarily the end. Not long after the magnetic method had been shown to work, it was suggested that it would be possible to get a similar process starting at the present lowest temperature and going down again by the same sort of factor to something near a millionth of a degree. The effective system was to be the magnetism in the nucleus of the atom. A good many atoms have magnetic nuclei, and their strengths are about a thousandth of those we have been discussing, and this is exactly what is wanted. The proposal was to take a diamagnetic salt of a metal of this character and work with that. The experiment was not going to be easy, because it was necessary to cool this specimen to the thousandth of a degree *in* a magnetic field by contact with a paramagnetic which had already been cooled so far by being taken *out* of the field; for this a long heat-conducting channel would be essential, and this channel, probably of liquid helium, must itself also be lowered to the temperature.

Theory, however, suggested a curious difficulty. For the process to work, it is not sufficient merely to get the energy out of the magnets, but these magnets must also be able to borrow the energy from the rest of the system so as to restore equipartition; for if they do not, we cannot say the temperature has really been lowered. It is true that at this stage there is scarcely any energy left except in the magnets themselves, but still there is some, and unless the right proportion of this is duly borrowed to restore equipartition, we cannot say that the temperature has really been lowered—for example, we could not chill a second body by placing it in contact. Now theory shows that the rate of this borrowing will depend enormously on the temperature. At 1° it is instantaneous, at a thousandth it takes seconds or minutes, but at a millionth it may easily take a million years. The heat insulation has, so to speak, become so good that different parts of the same molecule can be at different temperatures for a million years without the heat flowing from one to the other. But the same work that revealed this difficulty showed a way out. The structure of a metal is very different from that of a salt, in that, however low the temperature, there are always electrons moving about in it at high speeds—this does not contradict equipartition, but I must take that for granted. These electrons act as middle-men and succeed in bringing about equipartition quite rapidly. So it seems likely that perhaps in a few years, by the use of a metal in which the nuclei have a magnetic moment, it may be possible to reach temperatures down to perhaps a hundred thousandth, perhaps a millionth of a degree.

What will be the properties of matter there? Frankly, I do not think it likely that they will be very sensationally different from those already found at a thousandth. There are a few things we would like to know—for example, whether other metals become super-conductors besides those already found at 1°. It would also be nice to know whether the paramagnetics become permanent magnets, though I doubt if that is feasible because of the slow rate they would have in coming to equipartition with the cold body. But Simon has suggested another more remarkable idea about such temperatures, and this is that the whole idea of temperature itself fades away.

For temperature to have a practical meaning, one must be able to take the temperature of a body with a thermometer. Now this implies that the thermometer must be smaller than the body of which it is measuring the temperature, for otherwise it will itself disturb the body's heat. But there is now so little energy in the whole body that most of the time the thermometer will have none at all, and then occasionally will have much too much. To understand why this is so I may return to my metaphor of the doctors. The town is now so poor that its total capital only amounts to a few of the cheapest doctors' fees. Most of the time no one has enough money to pay a fee, but occasionally someone scrapes enough together and consults a doctor. Obviously we shall get a very different account of the health of the community according to whether we ask the fortunate doctor who has just got a fee, or one of the other members of his profession. The indefiniteness is, however, a matter of size. If we consider the health of a much larger town, or of a whole country, we shall find that there are a good many doctors who have got fees, and by averaging over them we could get an idea of the health of the community. So if we want to speak *usefully* of temperature at these very deep temperatures we must take a large body, and the colder the temperature the larger the body must be. Actually this region of indefiniteness is even now not at all far off. The first substance to show the effect would be a diamond, and it can be shown that a grain of diamond dust which is just visible will have a quite indefinite temperature at the temperatures already reached.

We seem to be ending on an anticlimax. Each successive stage in producing cold has called for greater efforts and has on the whole produced less results. In the first stage we leave all the rich variety of physical and chemical activity of ordinary temperatures—incidentally the activity that makes life possible—for the austere region of liquid helium. Here we have lost all chemistry, and have only found as compensation the interesting phenomenon of diminished specific heats and the startling fact of superconductivity. In the second stage, of paramagnetic demagnetization, there seems even less novelty, and the chief interest is in whether things will become permanent magnets. In the third stage, of nuclear demagnetization, we can not know what will happen, for it still lies in the future, but the most likely thing is that the target we are aiming at will simply fade away into indefiniteness before us.

THE ROYAL BOTANIC GARDEN, CALCUTTA

By Dr. K. Biswas,

Superintendent of the Garden

THE Royal Botanic Garden, Calcutta, situated on the bank of the River Hoogly only a few miles from Calcutta at Sibpur, offers a remarkable parallel to the Royal Botanic Gardens, Kew, which is situated on the bank of the Thames and is only a few miles from London. Both the gardens are of high scientific interest as well as of great æsthetic beauty. Both of them serve as a source of inspiration, education and research for their many visitors. To quote Sir Arthur Hill's words: "May they find in them both spiritual rest and refreshment and also that tree whose leaves were for the healing of nations".

But the Royal Botanic Garden, Calcutta, has a somewhat different origin from the Royal Botanic Gardens, Kew, which are younger than the Calcutta Garden by about fifty years. The latter started with a little more than three hundred acres of land. At present, it occupies an area of 273 acres.

Col. Robert Kyd of the Bengal Infantry, the then superintendent of the Honourable Company's dockyard and secretary to the Military Board of Fort William, a keen horticulturist, suggested on January 1, 1786, to the Governor-General, Sir John Macpherson, then officiating as Governor-General in the absence of Warren Hastings, the formation of a botanic garden in Calcutta. Without further delay effect was given to Kyd's proposal, and with the subsequent approval of the Court of Directors in England the present site, then measuring about 310 acres, immediately below Kyd's private gardens, was acquired. Col. Kyd very appropriately was also appointed as the honorary superintendent, and the work of developing this area into a botanic garden commenced with Kyd's valuable collection of exotic plants. The Garden was henceforth the property of the East India Company but under the control of the Governor-General-in-Council. This is the reason why the garden is still known among local people as the 'Company Bagan'. When the East India Company dissolved, all the rights, duties, and privileges were assumed by the Crown, and the garden became Her Majesty's Botanic Garden. Apparently on the constitution of the Province of Bengal in 1834, the control of the Garden passed on to the local government. The epithet 'Royal' came to be applied to it after the Queen's Proclamation of 1857. Kyd continued to perform the duties as superintendent until his death in 1793.

Dr. William Roxburgh, the Company's botanist in Madras, was appointed as the first official superintendent in 1794. He was the first to draw up a catalogue of 3,500 plants then growing in the Garden. This catalogue, "Hortus Bengalensis", in two parts, was published after Roxburgh's departure from India in 1813 by his friend Carey, the celebrated missionary. Roxburgh's "Flora Indica", his "Plantae Coromandelianae" composed of three volumes, and his magnificent large portfolio of coloured illustrations numbering 2,382, embodied in thirty-five volumes prepared during his period 1794–1814 with the help of Bengali artists, forms the basis of Hooker's flora of British India and many subsequent works on Indian plants. Roxburgh's work fully entitled him to the title of 'the father of Indian botany'. The famous scientific society under the title of the "United Brotherhood" was established at this time by Roxburgh's preceptor, John Gerard Koenig, a pupil of Linnæus, who was the guiding spirit of botanical studies in India.

In 1817, N. Wallich, an able and energetic botanist, was appointed and he held office until 1846. At his time the eastern portion of the Garden, measuring forty acres, including the teak plantation, was given up by the Government to the Lord Bishop of Calcutta (Dr. Middleton) as the site for a Christian College known as the Bishop's College. This college, since 1880, has been the Bengal Engineering College, Sibpur. In 1836, about two acres of land were allotted to the Agricultural and Horticultural Society of India, which was founded in 1820 by William Carey, its first president. This area expanded to about twenty-five acres, where the Society, in co-operation with the Garden officers, conducted the greater part of its work for about forty acres until 1872, when the Society's garden was transferred to its present site in Alipur.

Dr. Nathaniel Wallich undertook an extensive survey of a large part of the Indian Empire, particularly in the little-known regions of Kumaon, Nepal, Sylhet, Tenasserim, Penang and Singapore. His enormous collections were catalogued and named in Europe by himself, with the help of other botanists. They were then distributed to all the leading botanical institutions in Europe. A more or less complete set of this valuable collection, however, is still in the Calcutta Herbarium, together with Wallich's voluminous catalogue and his correspondence during 1794–1829, which were transferred to the Calcutta Herbarium from India House, London. Through the munificence of the East India Company, Dr. Wallich published his "Plantae

Asiaticae Rariores", three superb volumes of illustrated coloured figures.

Dr. Wallich, who was not only superintendent of the East India Company's gardens but also professor of botany at the Medical College, Calcutta, and superintendent-general of the Government Teak Plantation in Bengal, retired after thirty years of service in 1846 and died in 1854. He was followed by Hugh Falconer, a palæontologist, who held office until 1855. Early in 1848, during G. McClelland's officiating period, Sir Joseph Hooker visited the garden on his famous journey to Sikkim, and again on his return to Calcutta in 1850.

Falconer was succeeded by Dr. Thomas Thomson, a traveller and a botanist of much ability. Dr. Thomson was also president of the Agri-Horticultural Society (1859–1860), the coadjutor of Sir Joseph Hooker in the collection and distribution of an extensive and well-known herbarium of East Indian plants and the joint author of the first volume of the "Flora Indica". Thomson retired in 1861 and was succeeded by Dr. Thomas Anderson, whose untimely death in 1870 was caused by a disease contracted during his effort for the introduction of quinine-yielding cinchonas into the Sikkim Himalayas. Dr. Anderson was not only superintendent of the Royal Botanic Garden, Calcutta, and professor of botany but also the first conservator of forests for Bengal and in charge of the introduction and cultivation of cinchona in India.

In 1864 occurred the great cyclone of Calcutta. It was accompanied by a storm wave from the River Hoogly which laid the greater part of the Garden under water, in some places to a depth of six or seven feet, and carried two ships into the Garden with great violence. More than a thousand trees—at least one half of the total number in the Garden—and innumerable shrubs were prostrated. The survivors were much shattered, and scarcely a vestige of leaf, flower or fruit remained. Three years later a less severe but still very destructive cyclone, in which more than 760 of the surviving trees were blown down, completed the ruin. The removal of the wreckage occupied most of Anderson's remaining time in the Garden, but before he left in 1868 he had planned and begun to give effect to the planting of the Garden on a more or less formal systematic arrangement.

In 1871 Dr. (afterwards Sir) George King took charge of the Garden, which was not in a promising state. Sir George began the remaking of the Garden. The whole extent of the grounds was raised in level, the necessary soil having been obtained where large sheets of ornamental water have since been placed. These artificial lakes have been connected with each other by underground pipes, and a steam pump (and now an electric pump) has been supplied, by which the water in the whole system can be set at a high level by means of water pumped up from the river. Numerous wide roads have been made through the Garden. Many footpaths have also been made. The bamboo and mat erections which used to do duty as conservatories have been replaced by three large structures of iron. The valuable collection of dried plants has been suitably housed in a building designed by Mr. E. J. Martin, the Government architect. The internal arrangements of this building are adapted from those of the new Herbarium building at Kew.

King made remarkable contributions to Indian botany, and initiated the publication of the *Annals of the Royal Botanic Garden, Calcutta,* in 1887; vol. 14, Part 2 appeared this year. Sir George also moved at this time for the establishment of the Botanical Survey of India, which originated in 1890; the first record of the Botanical Survey of India appeared in 1893.

Lieut.-Colonel (now Sir David) Prain, who was first appointed as curator of the Herbarium, succeeded Sir George King, who after twenty-six years of meritorious service retired in 1897 and became the director of the Royal Botanic Gardens, Kew. Before Sir David left India in 1904 he sketched out a geographical

PALMETUM OF THE ROYAL BOTANIC GARDEN, CALCUTTA.

plan of garden divisions in accordance with which future plantings were to be regulated. Sir David Prain's plan, with slight modifications, has continued to be carried on by his successors as opportunity allowed up to the present day. Sir David retired on July 30, 1906, and took over the directorship of the Royal Botanic Gardens, Kew.

Lieut.-Colonel A. T. Gage was also first appointed as curator of the Herbarium and then succeeded Sir David in 1906. A catalogue of non-herbaceous phanerogams cultivated in the Royal Botanic Garden, Calcutta, prepared during Gage's time was published with the object of facilitating the exchange with other botanical institutions of plants, seeds, or materials for systematic, anatomical, physiological or chemical investigation. Gage was also professor of botany in the Medical College, Calcutta. He retired in 1923. During his absence on leave in 1908 Mr. W. W. Smith, now Sir William Wright Smith, keeper of the Royal Botanic Gardens, Edinburgh, and professor of botany in the University, who was then the curator of the Herbarium, officiated as the superintendent. Afterwards Mr. C. C. Calder was appointed as curator of the Herbarium after Smith. Mr. Calder succeeded Gage in 1923 and retired in December last year.

In the open garden there are about 15,000 trees and shrubs. In addition to these there are several thousand herbaceous species in the palm houses, orchid-houses and ferneries. The Garden, however, is by no means so rich in species as it might be, the total number of species in the open probably not exceeding 2,500.

The scheme adopted thirty-four years ago was to treat the Garden as a map of the world on Mercator's projection representing the tropical floras. The plants of India and Burma are to occupy the central triangular area of the large western part of the Garden, this area being again subdivided in accordance with the geographical subdivisions of the Indian Empire. To the west and south-west of the large central Indian area are the divisions for north-west Asia, Europe, then America, Africa, and Madagascar, and to the east of it the divisions for north-east Asia, China, Japan, the Philippines, Thailand (Siam) and Annam, the Malaya Peninsula and Archipelago, and Australasia, the last five being separated from the large central Indian divisions by the special collections of palms, screw-pines, and bamboos. Scattered throughout the Garden are twenty-six irregular lakes, some of which are of large extent with islands. Altogether the lakes comprise about one-ninth of the total area of the Garden. Most of them were designed by King with such skilful diversity of outline and surroundings as to enhance very greatly the beauty of the garden.

The work of both the Herbarium and the Garden is dependent to a considerable extent on botanical explorations. For this reason, the Botanical Survey of India evolved from the Botanical Garden. The work of the Botanical Survey of India and of the Garden with its Herbarium are so much interdependent that since the inception of the Survey in 1890 the superintendent of the Royal Botanic Garden has been the *ex-officio* director of the Botanical Survey of India. Botanical exploration is essential for utilizing the vegetable resources of the country and maintaining the vitality of the Herbarium and the Garden. A glance at a map of India showing the explored and unexplored regions will indicate what an enormous amount of work in this direction remains to be done.

The Herbarium and the Library have been developed since the foundation of the Garden in 1786. The present damp-proof and fire-proof building, especially designed to house nearly two and a half million sheets of herbarium specimens which form the basis of all botanical and allied investigation, was erected in 1883. In this Herbarium are a very complete collection of the dried materials of plants of the whole of the Indian Empire and also fair collections of those of Asia

OREODOXA AVENUE IN FRONT OF THE RIVER GATE OF THE ROYAL BOTANIC GARDEN, CALCUTTA, BEING THE KYD MONUMENT.

outside India, of Europe and Australia. Plants of Africa and America are far less perfectly represented. The Herbarium is an essential adjunct to a botanical garden of this standard.

Introduction of quinine, rubber, ipecacuanha, various timber trees, fibre- and oil-yielding plants and other plants of great economic value is mainly due to exploration by the scientific officers of the Garden. Almost all the road-side trees and ornamental garden plants now found widely growing throughout India and Burma were first acclimatized in this Royal Botanic Garden. They were then distributed all over India and abroad. Of recent introduction is the tung oil tree, which is a source of considerable revenue in China. Experiments at this Garden indicate possibilities of cultivation of tung oil in suitable areas of Bengal in the drier lower ranges of the Himalayas at 2,000–5,000 ft. There is no reason why India should not be made self-supporting with regard to the supply of this oil, so useful for various purposes. The Garden distributes seeds to various parts of India.

The garden roads were never intended for the heavy traffic that daily passes over them. In this sense the Calcutta Gardens must be unique. In most Gardens of similar dimensions and with similar objects the visitor passes on foot ; the restrictions placed upon him read very much alike wherever one goes. Custom and long precedent have allowed greater latitude to the visitor to Sibpur. Except in some of the nursery plant houses he can wander where he likes ; he picnics anywhere and he even lights fires in approved spots when he wishes to cook his food. It is all to the benefit of the Garden, in that greater public enjoyment and therefore support is ensured, and on the whole it must be said advantage is not taken of the latitude allowed.

OBITUARIES

Mr. H. J. Carter

BY the death of Herbert James Carter on April 16, Australia has lost one who had taken a prominent part in both educational and scientific affairs. He was born at Marlborough, Wilts., on April 23, 1858, the son of James Carter, and was educated at Aldenham School and the University of Cambridge, where he was a scholar of Jesus College. He was a mathematics master at Sydney Grammar School during 1881–1901 and was principal of Ascham Girls School from then until 1914. He was president of the Linnean Society of New South Wales during 1925–26, and a member of its Council from 1920 until 1939 ; also a fellow of the Royal Entomological Society of London. For many years he was honorary entomologist to the Australian Museum. He was science editor of the "Encyclopædia of Australia" published in 1926, and author of "Gulliver in the Bush" in which he related many of his experiences in pursuit of his scientific work.

Carter's special work was with the Australian Coleoptera, especially the families Tenebrionidæ, Buprestidæ, Cistelidæ, and Dryopidæ. In addition to descriptions of large numbers of new species, he paid particular attention to matters of synonymy, and published a number of check-lists of the families, and revisions of the Australian species of various genera. He did not shirk the drudgery of the work on synonymy, but often deplored the practice of some European colleagues who, on what he considered inadequate evidence, described large numbers of Australian species as new, and so added to the difficulties of Australian coleopterists.

His papers appear in a number of scientific journals from 1905 onwards, chiefly those of the Linnean Society of New South Wales, the Royal Zoological Society of New South Wales, and the Royal Society of South Australia. His last completed work was a short note on Dryopidæ, handed to the Linnean Society of New South Wales only a few days before his death, with the comment that he found such small objects trying to his sight and that this would probably be his last contribution on the family. His fine collection of Australian Coleoptera, including many types, will go to the Division of Economic Entomology of the Council for Scientific and Industrial Research at Canberra. A charming personality, he left a host of friends in his scientific colleagues and in his former pupils now scattered throughout Australia.

Prof. C. L. Boulenger

PROF. CHARLES L. BOULENGER, who died on May 21, aged fifty-five, will be remembered as a successful professor, an authority on freshwater medusæ and the trainer in helminthology of a large band of biologists who were scattered through the East for disease diagnosis in the War of 1914–18.

His father was G. A. Boulenger, F.R.S., a Belgian who became a great authority on reptiles and fish at the British Museum (Natural History). The son was a scholar of St. Paul's School and entered King's College, Cambridge, in 1903 as Lawrence Saunders scholar. He obtained first classes in the Natural Sciences Tripos and in 1906–7 occupied his University's table at the Stazione Zoologica, Naples, for the study of medusæ. He then visited Birket el Qurun (the remains of Lake Moeris) to investigate its medusa, discovering that its stinging cells are formed in the endoderm of the manubrium and in the ectoderm of the swellings at the bases of the tentacles before migrating to accumulate in surface batteries in the manubrium and tentacles respectively. This work was followed up by nine reports on medusæ from Tanganyika, Rhodesia, the Limpopo and the Caspian, chiefly concerned with their development and meristic and genetical variation.

After a year's demonstrating at Oxford, Boulenger returned to Cambridge in connexion with the museum, also demonstrating, particularly taking charge of Sir Arthur Shipley's advanced classes on the flatworms, nematodes and other parasites. In 1910 he went to Birmingham as lecturer and three years later was appointed reader in agricultural zoology. This was preceded by important work on the Myzostomida, external parasites of starfish, of which he received 170 specimens collected by Crossland from the Red Sea, this collection about doubling the known specimens. They were referred to six species with a full account of their anatomy. A report on a sheep's nematode (Nematodirus) followed, important for the development of cultural methods that enabled him to present its full life-history.

In 1915–16, Boulenger, under the Royal Society's scheme, lectured and demonstrated at Cambridge on the higher parasites of man. He then proceeded to Basra (Captain R.A.M.C.), where he acted as referee for worm parasites while making routine examinations for amœbic dysentery. He tabulated the stools of 1,180 patients, finding the British (about a third) quite free, while of the whole number 18·5 per cent had hookworm, 5·2 per cent Ascaris and 5 per cent Trichiurus, not large numbers, since Turkish prisoners proved to have four times these infestations. Unfortunately, he contracted amœbic dysentery, but in 1920 returned to India as professor at Lahore, working in the Punjab Veterinary Laboratory and specializing in the strongylid parasites of camels and horses. In 1921 he was appointed professor at the Bedford College for Women. To this he gave all his powers, fighting ill-health, for he never recovered from his Mesopotamian breakdown. He never married.

As a student Boulenger was very competent, but shyness caused him to be a solitary person and to build up a life within himself, ceramics and mezzotints then attracting him. This character he never lost, and perhaps it is the key to his life, if coupled with a strict obedience to duty. His lectures were models of clarity and balance, relieved by a marked touch of humour. He kept a high standard before his students, but was singularly understanding of their difficulties and always helpful; as an examiner he was remarkable for his judgment and appreciation of originality. With Prof. D. Mackinnon he effectively collaborated in providing a course in parasitology for the University of London. Every year he sent one of his students to Plymouth, providing anonymously the necessary funds by means of a prize. He was an admirable colleague, his views on college policy sound and strongly held. As he grew older his health became worse and he only found relief in the 'long' vacations at Algeria and Tangiers where he almost lived in the sea. In the winters he had his ticket for Covent Garden and gave play to his collector's instincts, especially in philately and oriental jewellery. J. S. G.

Prof. Michael Siedlecki

PROF. MICHAEL SIEDLECKI, who, during the occupation of Cracow by the Germans in November 1939 was imprisoned with the majority of the professors of the Jagellonian University, and transferred to the concentration camp in Oranienburg near Berlin, died there in January 1940.

Prof. Siedlecki was professor of zoology and director of the Zoological Laboratory and Museum of the Jagellonian University of Cracow, member of the Polish Academy of Sciences, honorary doctor of the University of Strasbourg, and member of many Polish and foreign scientific societies, including the Zoological Society of London. He was born in Cracow in 1873, and having taken the Ph.D. of the University of Cracow in 1895, he spent some years abroad completing his studies in zoology in the Universities of Berlin and Paris and at the Zoological Station in Naples. After his return to Cracow he continued zoological research in the University, first as an assistant, then as a lecturer in 1900, and finally as a professor without a chair. During 1908–9 he made a scientific expedition to Java and in 1912 succeeded Prof. Antoni Wierzejski in the chair of general and systematic zoology at the Jagellonian University.

In 1919, Siedlecki went to Vilna, to organize the new Polish university there, and remained until 1921, as the first rector of the University. He then returned to Cracow, to his former post as professor of zoology. Since 1923, Prof. Siedlecki represented the Polish Government on the Conseil Pérmanent International pour l'Exploration de la Mer in Copenhagen. He devoted much time to the organization of the Polish fisheries in the Baltic, and in the North Sea. He also organized the scientific investigation of the Baltic adjacent to the Polish sea-coast. Thanks to his efforts the marine stations at Hel and Gdynia were formed as the centre of scientific research of marine biology in Poland.

Most of Prof. Siedlecki's scientific researches concerned protozoology, especially the parasitic protozoans of the groups Sporozoa and Flagellata. He discovered and described a number of new and very important facts concerning the structure and development and reproduction in these groups, which are frequently cited in treatises and text-books on zoology. He was also interested in many other problems of animal biology, as is evidenced by his studies on tropical insects and amphibians. In the last years of his life his research was devoted almost entirely to marine biology, particularly to the biology of fishes inhabiting the North and Baltic Seas.

Prof. Siedlecki also took a great and active interest in the preservation of wild life. He organized the Polish Section of the International Committee for Bird Preservation, and was its chairman until 1937.

when, though still taking a prominent part in the work, he relinquished his position to Prof. Count Kasimerz Wodzicki. He was a member of the subcommittee appointed by the International Committee for Bird Preservation to examine and coordinate the proposals put forward by the National Sections of Europe for the Revision of the International Convention for the Protection of Birds (Paris 1902), and presided over many of its deliberations. He represented the Polish Government at the International Ornithological Congresses in Amsterdam in 1930 and in Oxford in 1934. Prof. Siedlecki's knowledge of international affairs, his diplomacy and his personal charm were of inestimable value at the many international meetings he attended; he was deeply respected by everyone with whom he came in contact, of whatever nationality, and those who had the privilege of working with him will always remember him with a lasting affection. Prof. Siedlecki was a man to whom the word 'cultured' could be applied to its utmost meaning, from his great knowledge of art, literature, architecture and history to his gentleness and courtly manner. But above all Siedlecki was a patriot, and his burning love for his country was an inspiration.

We regret to announce the following deaths:

Prof. L. S. Bagster, professor of chemistry in the University of Queensland, Brisbane, aged fifty-three.

Sir Arthur Harden, F.R.S., emeritus professor of biochemistry in the University of London, formerly head of the Department of Biochemistry in the Lister Institute, on June 17, aged seventy-five.

Prof. Samuel Klein, professor of the historical geography of Palestine in the Hebrew University, Jerusalem.

Dr. G. A. Loveland, formerly chief meteorologist of the Boston Weather Bureau, on March 30, aged seventy-six.

Dr. E. F. Northrup, vice-president and technical adviser of the Ajax Electrothermic Corporation, formerly assistant professor of physics in Princeton University, on April 29, aged seventy-four.

Prof. F. H. Probert, dean of the College of Mines, University of California, on May 9, aged sixty-four.

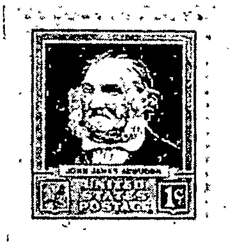
Prof. R. H. True, emeritus professor of botany in the University of Pennsylvania and director of the Morris Arboretum, who was known for his work in plant physiology, on April 8, aged seventy-three.

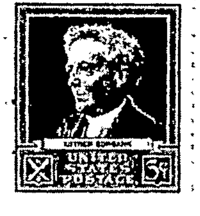
NEWS AND VIEWS

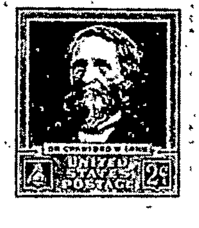
Commemorative Stamps to American Science

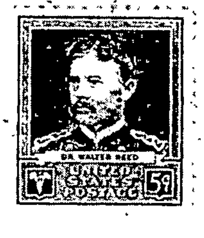
A new one-cent stamp in honour of Audubon was issued in St. Framisville, Louisiana, on April 8. J. J. Audubon (1785–1851), the well-known naturalist son of a Frenchman, worked almost solely on American animals, his greatest work being "Birds of America". This work contained 435 hand-coloured plates with 1,065 life-sized figures of 489 distinct species of birds. Audubon was the pioneer in the portrayal of birds in their natural positions and environment. The three-cent stamp in honour of Burbank was issued in Santa Rosa, California, on April 17. Luther Burbank (1849–1926) was the famous American plant breeder. Most of his work was carried out at Santa Rosa, which he described as "the chosen spot of all this earth as far as Nature is concerned". His most important early work, in 1872, was that of the development of the Burbank potato. Later, he worked successfully on the plant genera Rubus and Prunus.

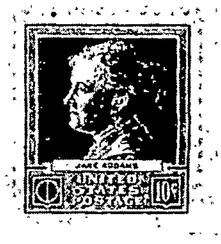
Dr. Crawford Long (1815–1878), in whose memory a two-cent stamp was issued in Jefferson, Georgia, on April 8, was a pioneer in the use of ether as an anæsthetic. He administered ether for the first time in surgical history on March 30, 1842, in an operation for the removal of a tumour from the neck. The first account of his discovery was published in 1849. Dr. Walter Reed (1851–1902), the American bacteriologist attached to the army, disproved the then prevalent theories of the transmission of yellow fever and finally succeeded in showing that the parasite was transmitted by the mosquito *Stegomyia fasciata*. He also showed that the bite was effective only under certain conditions. A commemorative stamp to the value of five cents was released in Washington on April 17. A ten-cent stamp in honour of Jane Addams, the American sociologist, has also been released. Her greatest achievement was the establishment of the well-known social settlement, Hull House, in Chicago.











The *Bulletin Analytique*

THE *Bulletin Analytique* is a journal of abstracts, issued by the French Government's new Service de Documentation (see p. 947). The director of the Service is Prof. P. Auger, and the chief editor of the *Bulletin* is Dr. N. Thon. The Bulletin was to have been issued in fortnightly parts. The first six parts, for January–March of this year, have been published in one fascicule. Nos. 7–8 appeared in April and No. 9 is dated May. The size of the page is about 6¼ in. × 9½ in. It is hoped that a complete annual volume will contain about one thousand pages. The abstracts are classified under eighteen subjects, which are : mathematical physics ; corpuscular physics ; structure of solids and liquids ; mechanics and heat ; radiation and optics ; electricity and magnetism ; astrophysics and geophysics ; thermodynamics and chemical statics and dynamics ; electrochemistry, photochemistry, radio chemistry, and photography ; colloids and adsorption ; chemistry of minerals, mineralogical chemistry and geochemistry ; organic chemistry ; metallurgy ; industrial chemistry and materials ; agricultural chemistry ; biological chemistry ; agriculture ; physiology. The titles of all papers and all abstracts are given in French, with the name of the author, the place where the research has been done, the journal in which it has appeared and the language of the original. Abstracts of unpublished papers in the Service's archives are given a special mark.

Emile Duclaux

PROF. PIERRE EMILE DUCLAUX, the well-known chemist and bacteriologist, was born at Aurillac, capital of the Cantal Departement of France, on June 24, 1840. In 1857 he went to Paris, where he was educated at the Lycée Saint Louis. Two years later he passed the entrance examination not only at the Ecole Polytechnique but also at the Ecole Normale Supérieure, where Pasteur, with whom he became closely associated, was sub-director of scientific studies. In 1862 he became an *agrégé* and assisted Pasteur in his investigation of the disease of silkworms which was then prevalent in several departments of France. In 1865 he was appointed professor of chemistry at Tours, from which he was transferred in a similar capacity to Clermont-Ferrand, where he had about a hundred pupils, most of whom were medical students, including Emile Roux, his successor at the Pasteur Institute. From Clermont-Ferrand he went to Lyons, where he remained five years as professor of physics. Finally he settled in Paris in 1878 as professor of physics and meteorology in the Agronomic Institute.

In 1886, Duclaux was appointed professor of biological chemistry at the Sorbonne and held this position until his death. In 1888 he was elected a member of the Academy of Sciences in the section of rural economy, and in 1894 he became a member of the Academy of Medicine. In 1895 he was appointed Pasteur's successor in the Institute in the Rue Dutot. In the words of Prof. H. Roger, "Duclaux possessed all the essential qualities of a professor—erudition, critical sense, a lucid style and a taste for polemics". He was a remarkably prolific writer. In addition to more than eighty articles dealing with molecular physics, chemistry, meteorology, enzymes, physiology of digestion, vegetable physiology, bacteriology, etc., he was the author of a number of books, including "Ferments et maladies" (1882), "Le Microbe et la maladie" (1885), "Pasteur, Histoire d'un esprit" (1896), which was translated into English in 1920, "Traité de Microbiologie" (1898–1901) and "L'hygiène sociale" (1902). He was also founder in 1887 of *Annales de l'Institut Pasteur*. He died on May 3, 1904.

Huxley's Teaching at Edinburgh

DURING the four years when the *Challenger* was sailing the oceans of the world, Sir Wyville Thomson left his natural history class-room in the University of Edinburgh to lead the expedition. The vacancy was filled temporarily by two naturalists of European fame—Julius Victor Carus, of Leipzig, who conducted the zoology courses in the summer sessions of 1873 and 1874, and Thomas Henry Huxley in 1875 and 1876. An account of their tenure of the natural history chair, by Prof. James Ritchie, appears in the summer number of the *University of Edinburgh Journal* (pp. 206–212), the information about Huxley being gathered mainly from the class roll-books, and from a small notebook of Huxley's dealing with "Lectures, Edinboro", in the Huxley Library of the Imperial College of Science and Technology. Huxley drew a crowded audience for his introductory lecture on "The Crocodile"—it was a free lecture—and he laments that many parsons were present who "came to curse and didn't remain to pay". His course proper, covering twelve weeks, traversed the whole animal kingdom from Protozoa to Mammalia, and was predominantly morphological and classificatory, although generally some reference was made to development and to the fossil record of a group.

It was a heavy programme, and Huxley as well as the students felt the rush and strain. Joseph Thomson, student in 1876, who became one of the greatest of the geographical pioneers in Africa, wrote, "Huxley's usual lectures are something awful to listen to . . . to master his language is something dreadful", and yet "I would not miss them . . . they are something glorious, sublime". Huxley's own impression of the course was equally definite. "I . . . positively polished off the Animal Kingdom in fifty-four lectures. French without a master in twelve lessons is nothing to this feat." The class roll-books show that a practical class in zoology was first held in 1872 under Wyville Thomson, but except for a short record in the University Calendar there is no record of the scope of the work of the earliest practical classes. Huxley's notebook indicates that the class, conducted by the assistant under the professor's supervision, examined fourteen different types, and Prof. Ritchie points out the curious fact that the practical class appears to have traversed the animal kingdom from Vertebrates to Infusoria almost in the reverse order from that adopted in the lectures.

The Religion of the Future

IN an article "Brave New World Planning" in the *Quarterly Review* of April, W. J. Blyton stresses the importance of such values as freedom with discipline, personal character, room for spontaneity and the spiritual as a basis for a new world order. Character and not mechanisms must come first, and only a better and stronger religion will overthrow the passionate and evil religions which at present menace the world. Without that, democracy will not be enough, and Mr. Blyton argues that the League of Nations failed because its foundations were legalist, secular and without spiritual appeal, moral authority, or imaginative hold on the stormy wills of men. No future order, he urges, will last unless it is viewed as sacred by a vast majority who have to live under it. It must be loved and valued as England (or other *patria*) now is ; as one's religion is ; or one's family, personality and liberty. A wave of moral conviction and spiritual vision must pass over many nations, and the comprehensive order will grow out of close, friendly but not firmly defined relations. The entire mundane political business hinges on virtue, which can be analysed into conscientiousness, sympathy, self-discipline and moral insight, and great and good achievements are not officially inspired by law, resolution, or orders. Education in the limited materialist, utilitarian sense of the word is nought. To roll back the tide of Belial and Moloch we must oppose a true religion, instinct with love, works of mercy, the new life, the inescapable mysteries of life and death.

Culture, Diet and Teeth

WHILE the excellence of the teeth of primitive peoples, in the sense of an absence of caries, even though the teeth may be much worn by rough or coarse food, has been a subject of frequent reference by travellers and anthropologists, it is infrequent that direct evidence is available of the relation of diet and state of the teeth to which this character in the people is referred, usually in quite general terms. Yet obviously the question is one of considerable importance in evaluating the sum total of the effects of changes in culture which have recently taken place and are continuing among peoples of backward civilization in their contacts with Europeans.

A valuable observation of the mechanism of dental deterioration through cultural change is afforded by the field observations of Dr. Helen Mellanby of the University Field Laboratories, Sheffield, on the teeth of a number of Finnish Lapp children, reference to which is made on p. 978. Among these children a remarkable degree of dental hypoplasia appears and, as was to be anticipated, this was accompanied by an equally high percentage of carious affection. The interest and significance of the observations, however, was enhanced by a fortunate opportunity for comparing a part of this material with teeth from skulls from the same group of Lapps, dating back from fifty to two hundred years, in the Helsinki Museum. As compared with the teeth from this source, the teeth of the modern children showed a marked deterioration in structure, and a similar impression was conveyed by the teeth of the adult skulls, as compared with the teeth of the modern adult population, though no exact observations were made.

It has been shown that the structure of the teeth is dependent to a large extent on diet, and in attempting to account for this very evident deterioration in the structure of the teeth of modern Inari Lapp children, Dr. Mellanby puts forward the suggestion that while Inari Lapp culture has suffered less change than that among any other body of Lapps, their diet, which formerly was based upon a reindeer cultural economy and was almost entirely carnivorous without bread, has now become one based on mixed farming with reindeer keeping, in which the diet depends upon 'civilized' substitutes with large quantities of cereals. Comparative figures from Greenland quoted by Dr. Mellanby may be interpreted in like manner as emphasizing the effect of cultural change in an alteration of diet as affecting the character and health of the teeth. While the teeth of the children of the remote parts of East Greenland are probably the least carious of any (excluding the tropics), those of West Greenlanders, who are 'civilized', are slightly worse than those of children of the Danish elementary schools, among whom defects of 31 per cent for deciduous and 34 per cent for permanent teeth have been recorded.

Plant Foods of Australian Aborigines

IN a reference to a publication made some time ago by Mrs. I. W. Dadswell (*Austral. J. Exp. Biol. and Med. Sci.*, 12, 13 (1934), Sir James Barrett points out that all the useful plants and animals now established in Australia were imported. The criticism that the aborigines never cultivated a plant nor domesticated an animal as a source of food is equally applicable to Europeans, in so far as the indigenous flora and fauna are concerned. Yet the aborigines, whom we are accustomed to regard as an uncivilized vestige of the Stone Age, have adapted themselves to their environment so as to be able to live and thrive where Europeans would starve. Thus, Governor Phillip had to ration the first settlement at Sydney Cove in 1788 ; and white men lost in the bush have usually perished unless helped by aborigines.

Mrs. Dadswell, working in the Department of Biochemistry of the University of Melbourne, found that certain vegetable foods eaten by the natives of Central Australia, and collected near Mt. Liebig in the Alice Springs region, do not differ greatly from corresponding cultivated foods in their organic composition, and that the necessary inorganic constituents, with the exception of phosphorus, are plentifully supplied in these foods. Thus, the fruit of *Solanum ellipticum* is bracketed with the tomato, the root of *Portulaca oleracea* with the carrot, parsnip and turnip, the tuber of *Ipomœa* sp. with the sweet potato, and the leaves of *Celendrinia balonnensis* with cabbage, lettuce and spinach. The moisture content of the fresh native foods was lower than that of similar cultivated foods ; the total ash was higher ; calcium, magnesium and iron were abundant. In further investigations of the kind, which are contemplated, it would be of interest to include a reference to the vitamins of these native foods, and also to record any occurrence of sugars. According to the late Mr. H. G. Smith, of the Sydney Technological Museum, sugar in any form was a great attraction to the aborigines, who prized highly such sweet rarities as "Eucalyptus manna" (raffinose from certain punctured eucalypts) and "lerp" (a protective secretion of Psyllideæ).

Conservation in Canada

WRITING in the second issue of *Canadian Nature* (Whittemore Publishing Co., Toronto), Mr. Alan F. Coventry deals at length with an interesting experiment in conservation made on 88,000 acres at King Township, near Toronto. A survey of natural resources found the human population to be 4,600, and since 1840 the wild-life has decreased through human interference. The only large mammals left are deer on Holland Marsh; the imported European hare is one of the most abundant, first appearing in 1925, and the area seems to be the northern limit for winter survival of the imported ring-necked pheasant. Depletion of natural water supplies and need for reafforestation are also noted. It is pointed out that the findings of the survey are applicable to a large part of southern Ontario, and similar surveys to the King Township investigation are recommended for other regions, so that the information gained can be used for conservation and for remedies to overcome increasing tendency towards flood and drought dangers. In no more than a century, about 2,500 acres have been abandoned as no longer fit for cultivation.

Conservation apparently plays a large part in the purpose of *Canadian Nature*, but there is no superabundance of sentimentality which deters the scientific naturalist from so many publications related to wildlife. An account is given of the Federation of Ontario Naturalists' Summer School at Camp Franklin, Parry Sound, and Prof. J. R. Dymond, of Ontario Museum, writes the "guest editorial", which is apparently to be a feature by notable authorities.

Primitive Insects of South Australia

UNDER this title Mr. H. Womersley, entomologist at the South Australian Museum, in Adelaide, contributes a useful handbook (dated 1939) on the lower insects, or Apterygota, of the country named. Recognizing the need for a wider diffusion of accurate knowledge of the fauna and flora of this region, a committee, under the South Australian Branch of the British Science Guild, has undertaken the issuing of a series of handbooks. The absence of suitable reference manuals has been a real handicap to the progress of Australian biology, and those which have already been planned, or issued, are prepared gratuitously by South Australian biologists and geologists: they are printed and published by the State Government and are available for sale at low prices. Some fifteen of these handbooks have now been issued and others are in course of preparation. Mr. Womersley's work is the first of the series to deal with the Insecta and comprises accounts of the orders Thysanura, Collembola and Protura. Well printed and arranged, its numerous clear and mostly original illustrations form a special feature that greatly enhances the value of this handbook. Increase in knowledge of these primitive insects has been rapid: thus in 1932 no Protura had been recorded from Australia, whereas eight species are now known. In 1926 only about forty species of Collembola were recorded from Australia, but now Mr. Womersley accounts for more than two hundred species. The handbook is set up by the Government Printer, Adelaide, and is good value for its price, 7*s*. 6*d*.

The National Physical Laboratory

THE report for 1939 of the National Physical Laboratory covers 100 pages (London: H.M. Stationery Office. 2*s*. 6*d*. net). During the year there has been no great falling off in the experimental work done for, and the advice given to, industry both for immediate purposes and for long-range projects for opening up new possibilities, or in the testing of instruments or the maintenance of exact standards of measurement. But the War has raised new problems for solution which have come from the Services and the civil defence departments. Changes of staff to and from industry, to the Admiralty, the Air Ministry and the Forces have been more numerous than usual. Among the investigations of the year may be mentioned those on the physical properties of carbon steels, light aluminium and magnesium alloys, ship propellers, new aircraft, the reduction of sound transmission in buildings, electrical insulating materials and the propagation of ultra-short radio waves. Members of the staff have continued to give lectures on the work of the Laboratory at provincial centres, to serve on technical committees at home, and to attend international conferences on scientific and technical questions abroad.

Life Expectancy in the Philippines

IN a recent communication (*Acta med. Philippina*, 1, 217; 1940) emanating from the Institute of Hygiene of the University of the Philippines, A. G. Sison, H. Lara, M. M. Herbosa and A. A. Lozano have compiled an instructive paper illustrated by 25 tables and 12 graphs of the life expectancy in the Philippines in 1902 and 1918. Their conclusions are as follows. The average expectation of life for both sexes in 1918 was 26·5 years, as compared with 17·91 years in 1902, which meant an improvement of approximately 9 years. For males the average expectation of life was 17·56 years in 1902 and 27·15 years in 1918, the corresponding increase being approximately 10 years. In 1902 the average expectation of life for females was 18·67 years and in 1918 26·38 years, an improvement of approximately 8 years. The complete expectation of life in the Philippines at birth for males was 11·54 years in 1902 and 25·17 years in 1918, an approximate increase of 14 years. For females the complete expectation of life at birth was 13·92 years in 1902 and 26·07 years in 1918, the increase being 12·15 years. The complete expectation of life at birth for both sexes was 12·24 years in 1902 and 25·64 years in 1918, in other words, the average length of life remaining to each child born alive in 1918 was more than double that of 1902.

Raymond Sabouraud

THE specialist research worker in a limited field is not usually accorded a large share of public fame, even though his contributions be enlightened and fundamental. Raymond Sabouraud performed a surprising amount of original investigation, at the Pasteur Institute, Paris, into the fungi which cause skin diseases of animals. A paper by Dr. L. Grigoraki (*Mycopathologia*, **2**, Fasc. 3, 171–200; March 1940) indicates the historical setting of Sabouraud's activities, and shows how greatly the science of dermatology is indebted to him. Many of the skin diseases are caused by species of fungi belonging to the genus Trichophyton. No fewer than twenty-five species of this genus are from Sabouraud's original description, and his studies embraced the disease and its prevention, in addition to the causal parasite; X-ray therapy developed into a cure at his hands, with the help of his associates. Most eloquent of all, however, is the citation of Sabouraud's published works, which occupy twenty-four pages in the paper under review, and provide the only monument which their author appeared to desire.

Pest Infestation of Produce

THE Secretary of the Department of Scientific and Industrial Research announces that H.M. Government has gratefully accepted the offer of the Governing Body of the Imperial College of Science and Technology to place at the Department's disposal for the period of the War all the accommodation of the Biological Field Station at Slough that is required for the purposes of the Department's work on the infestation of produce by insects. The Department has now taken into its own employment the staff of the Imperial College hitherto engaged on the Department's work in this field, and with the consent of the Governing Body of the College has secured the services of Prof. J. W. Munro as consultant. All correspondence intended for the Department on the infestation of produce by insects should be addressed to the Officer-in-Charge, Pest Infestation Laboratory, Biological Field Station, Slough, Bucks.

Announcements

PROF. W. L. BRAGG will deliver the Norman Lockyer Lecture of the British Association at Hull on June 24.

PROF. S. S. BHATNAGAR, professor of chemistry at the University of Lahore, has been lent for two years to the Government of India as director of scientific and industrial research. Prof. Bhatnagar carried out research work at University College, London, under Prof. F. G. Donnan during the years 1919–21, and obtained the D.Sc. degree of the University of London. Since then he has built up a most successful school of research at the University of Lahore, and has himself made contributions to magneto-chemistry and other branches of modern physical chemistry, besides doing a great deal of important technical work.

ROBERT D. POTTER, news editor and staff writer in physics and chemistry for Science Service since 1934, has been appointed science editor of the *American Weekly*, a large magazine supplement distributed by many American newspapers in their Sunday editions. Mr. Potter received his B.S. degree from the University of Buffalo in physics in 1927. During 1928–32, he was a graduate assistant in the department of physics at the Washington Square College, New York University, and later became the science editor of the *New York Herald Tribune*.

THE Trustees of the Lady Tata Memorial Fund announce that, on the recommendation of the Scientific Advisory Committee, they have agreed, if circumstances permit, to make the following awards for research in blood diseases, with special reference to leukæmia, in the academic year beginning on October 1, 1940: grants for research expenses to Dr. M. P. J. Guérin (Paris), Prof. K. Jármai (Budapest), Prof. E. L. Opie and Dr. J. Furth (New York), and Dr. A. H. T. Robb-Smith (Oxford); part-time personal grant and grant for research expenses to Dr. Werner Jacobson (Cambridge).

THE Franqui Prize of half a million francs has recently been awarded by the Franqui Foundation Committee to Dr. Pierre Nolf, professor of pathology and therapeutics at Liège and member of the Belgian Royal Academy of Medicine, for his contributions to science. The former Franqui prizemen are Prof. Henri Pirenne, professor at Louvain, Franz Cumont, member of the Royal Academy of Science, and Jacques Errera, professor in the University of Brussels.

DURING 1939, 91 miners were certified to have died of silicosis and 355 certified to have been disabled by the disease in the South Wales coalfield.

A NEW institute for experimental hygiene has recently been founded at Montevideo, and will probably be connected with the Clinic for Infectious Diseases.

ACCORDING to Sir William MacArthur, Director-General of Army Medical Services, in spite of the severe winter there have been relatively few cases of serious illness among the troops and a very light incidence of acute infectious diseases.

THE number of road accidents in the Union of South Africa in 1939 was lower than for 1938 and 1937 despite the increased number of vehicles. The number of people killed was less than in any year since 1935, and in 18 chief towns it was the lowest for five years. The number of accidents was 43,205 in 1939 compared with 43,868 in 1938 and 45,947 in 1937.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 977.

Optical Sensitizing of Silver Halides by Dyes

IN a recent communication[1] we indicated the importance of planarity of dye molecules for the absorption of light and for photographic sensitizing. A further survey of cyanine dyes has shown this to be general; moreover, we find that dyes capable of planar form, but having strain on bond angles, show a *negative* temperature coefficient of absorption in solution. Increase of rotational-vibrational energy in the molecule overcomes the strain and relaxes the structure to a non-planar form. The activation heat can be equated to the potential energy of strain which is removed.

Using the same isomeric cyanine dyes previously described[1] we now have found that the planar isomers adsorbed to pure silver bromide (no gelatin) produce a normal photolysis (photo-chemical production of silver) on illumination in their absorption bands. But no photolysis was effected by the non-planar isomers, although they were equivalently adsorbed, that is, to an adsorption density corresponding to the area occupied per molecule—or molecular ion—in edge-on orthogonal orientation[2].

It appears that there is something fundamental and essential for optical sensitizing in this edge-on adsorption of *planar* dye molecules. In such molecules, the resonance and the electronic transition occurring on absorption of a light quantum are polarized in the plane of the molecule. In fact, in a great number of cases, the molecule may be regarded as a linear oscillator, so that, in consequence of the orthogonal orientation of the planar molecule to an octahedral (110) plane of the crystal, the electronic transit is polarized parallel to such a plane and in an azimuth normal thereto.

Optical sensitizing of silver halide can be shown now to exhibit some interesting analogies—perhaps close affinities—with the well-known 'selective' (external) photo-electric effect. This is an *external* effect, the electrons measured being those that pass the surface potential barrier, whereas the dye sensitizes an *inner* photo-electric process, namely, elevation of electrons from filled zones to conducting zones in the crystal. These internally liberated electrons may: (1) consummate photolysis by uniting with silver ions[2]; (2) spill over into contiguous silver metal-producing photo-voltaic effects[3]; (3) give actual photo-conductance[4] . . . in all cases for light absorbed by the adsorbed dye.

The similarities and differences between optical sensitizing and the selective photo-electric effect will be discussed in the fuller publication. The essential fact which we have brought out is that optical sensitizing not only involves a selective band (electronic transition) absorption of light, but also therewith selective polarization of the absorbed photon. The necessary and sufficient conditions for a dye to act as an optical sensitizer of silver halide appear to be:

(1) Oriented edge-on adsorption, orthogonal to a (110) plane of crystal;

(2) Planar configuration of dye molecule, respectively, of adsorbed dye ion;

(3) Electronic transition in dye ion on absorption of photon, polarized in an azimuth defined by (1) and (2).

We may suppose that the electrons of the filled (strongly shielded) zone (atomistically the Br^- ions of a 110 plane) have a vector, E_a in the 110 plane. This component may undergo partial coupling with a parallel component of the resonance energy of the adsorbed dye molecule polarized in the same azimuth. This corresponds to the displacement of the light absorption of the adsorbed dye molecule to lower frequencies than in the free, gaseous state. There is a corresponding enhancement of this component for an electron of the filled level, which becomes $E_a - h\Delta\nu$. On absorption of a quantum, $h\nu$, of light by the adsorbed dye, the coupling advances to the taking over of this whole increment of electronic oscillation, polarized in the same azimuth, by a partially coupled electron of the filled zone; the total kinetic energy of this electron in the given plane becomes $E_a + h\Delta\nu + h\nu \cong h\nu_0$, where $h\nu_0$ is the energy necessary to raise an electron to the conductance zone of the crystal. The condition becomes equivalent to that deduced by A. von Hippel[5] for dielectric breakdown in alkali halide lattices, in which it was shown that in these (cubic) crystals the electrons prefer to move through the lattice in the 110 plane.

Essentially, what is postulated is a sufficiently large coplanar component of the otherwise strongly shielded electronic energy of the filled zone to make up the energy necessary to free the electron on coupling with a photon absorbed by the dye molecule. We have shown that optical sensitizing is limited to precisely the most favourable conditions for this. The relation of the suggested mechanism to so-called metastable levels and disturbed lattice points will be discussed in the fuller publication, as also the interesting suggestion of J. Eggert[6] that in ordinary latent formation by ultra- and blue-violet light the more perfect lattice regions are acting as 'optical sensitizers' for perturbed or imperfect regions. The foregoing conclusions, derived for planar cyanine dye molecules, and 'molecular' sensitizing, are equally consistent with 'aggregate' sensitizing[2]. It has been shown that the adsorbed molecular aggregates are parallel-piled edgewise adsorbed ensembles of planar dye ions[2]. Also, it has been shown by E. E. Jelley[7] and by G. Scheibe[8] that filaments or packets of these parallel piled ions constitute a mesomorphic (initially nematic) phase of ionic miscelles. The new—and strongly shielded—electronic transition (shown in absorption, in fluorescence, and in optical sensitizing) proper to these ensembles is polarized in a direction perpendicular to the plane of the component molecular ions, that is, parallel to the axis of the packet or micelle—and, therefore, to a 110 plane of the crystal. The coupling of this with the azimuthal component of the electronic energy of a filled zone could proceed, therefore, as for an adsorbed molecule. In this connexion, it is significant that we find that non-planar cyanine dyes do not aggregate in the nematic state, while their planar isomers do so.

The considerations advanced are equally applicable to acid sensitizing dyes, for example, erythrosin, etc., of the xanthene type. These also are adsorbed edgewise and orthogonally to an octahedral surface, though of silver ions[2]. The molecules of these dyes are also planar, and *a fortiori*, because having a fused polycyclic skeleton.

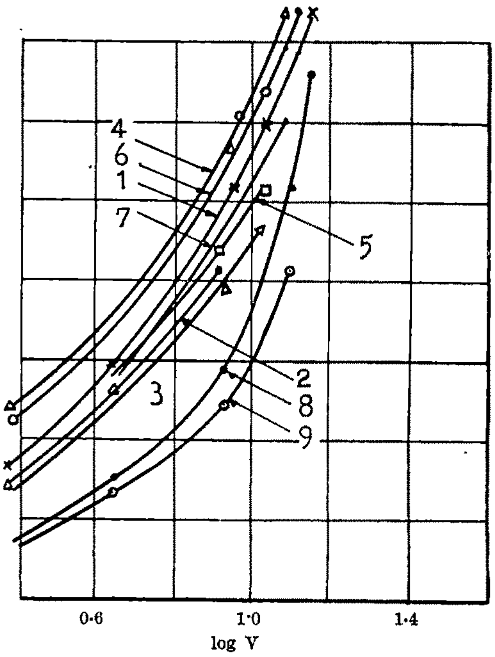
Viscosity of Suspensions and the Einstein Equation

THE Einstein equation $\eta = \eta_0 (1 + 2\cdot5\ V)$ relating the viscosity η of a suspension of solid spheres and η_0, the viscosity of the dispersion medium, V being the volume in parts of a cubic centimetre occupied by the dispersed solid, has been used as a basis for determining the molecular structure of proteins and other colloidal substances[1].

It is of interest in this connexion that the viscosity ratio η/η_0 is dependent, among other things, on temperature, the ratio being affected by the viscosity of the dispersion medium. The following data for (*a*) 16·7 per cent volume of graphite in a mineral lubricating oil and (*b*) 14·8 per cent volume kaolin in meta cresol, for example, illustrate this.

(*a*) Temp. ° C.	η	η/η_0	(*b*) Temp. ° C.	η	η/η_0
30	3·7	3·6	13·5	1·21	7·7
40	1·9	3·4	22	0·15	7·2
45	1·5	3·1	45	0·05	6·7

That the effect is not entirely due to disaggregation is indicated by using dispersion media of different viscosity. In the accompanying graphs, values of log $(\eta/\eta_0 - 1)$ and log percentage volume are plotted for powdered silica in various liquids, and it will be seen that the curves are roughly in order of the viscosity of the liquids, the viscosity ratios being least for normal hexane and greatest with glycerol. The source of the variation is presumably due to the spinning motion of the particles or their aggregates, less time being required in the thinner liquids for the dispersed phase to take up positions of streamline flow.



1, MINERAL LUBRICATING OIL ; 2, RICINOLEIC ACID ; 3, LIGHT MINERAL LUBRICATING OIL ; 4, GLYCEROL (91%) ; 5, POPPY SEED OIL ; 6, RAW LINSEED OIL ; 7, TRIACETIN ; 8, CARBON TETRACHLORIDE ; 9, NORMAL HEXANE.

It was found under isoviscometric conditions that the specific character of the dispersion medium affects the viscosity ratio ; thus, for example, with kaolin, 5 per cent volume, a viscosity ratio of 2·15 was found in a light mineral oil, but in oleic acid the ratio was 1·3 and in benzyl alcohol 1·45.

It is possible that in very dilute suspension these effects may be minimized, but in the systems examined at lower concentrations the variations were observed.

The viscosity measurements were made in a simple form of plastometer, low rates of shear being avoided.

Cohesion of Liquids

THE recent interesting letters of Profs. M. Born and R. Fürth, published in NATURE of May 11, on the strength of solids, lead me to think that experiments which I am now carrying out on the strength of liquids under hydrostatic tension may be of interest to physicists working in this field. Liquids, owing to their homogeneity and absence of rigidity, possess certain advantages over solids for the study of cohesion. In my view, measurements of the greatest tension which can be applied to liquids under various conditions have been rather neglected by physicists, particularly in recent years.

In my experiments, a form of apparatus has been devised in which a metallic bellows, closed by a needle valve, contains the gas-free liquid under test, and the possibility of inward leakage of atmospheric air is avoided by completely surrounding the bellows and valve by the same liquid. The needle valve being closed, tension is gradually applied to the liquid by slowly filling a suspended can by means of a small jet of water. The water flow is turned off the moment a sudden downward movement of the can indicates that the liquid has broken. The can is then weighed complete with the contained water, and the tension which existed in the liquid immediately prior to breaking is calculated from the known effective cross-section of the bellows.

The liquids so far examined by this method are alcohol, ether and lubricating oil. It would be premature to quote results in detail at the present stage. However, it appears that the maximum tension which the above liquids will withstand for long periods under the conditions described is simply related to their surface tensions and vapour pressures. The maximum tension increases as the temperature is lowered, and this increase can be largely explained by the changes in surface tension and vapour pressure.

Crystal Structure of Phosphorus Pentabromide

IT has been shown[1] that phosphorus pentachloride has an ionic type of crystal structure which is tetragonal and contains $[PCl_4]^+$ and $[PCl_6]^-$ groups. Phosphorus pentabromide is entirely different in crystalline form. It is orthorhombic, and X-ray investigations give for the unit cell $a = 5{\cdot}6$, $b = 16{\cdot}9$, $c = 8{\cdot}3$ A., with four molecules per unit cell. The space group is *Pbcm* and the four phosphorus atoms are therefore necessarily equivalent crystallographically and chemically. The possibility of a structure containing two different complexes similar to those in phosphorus pentachloride does not arise in this case. It is impossible to fit in four molecules of PBr_5 of the trigonal bipyramidal form, and the appearance of the diffraction patterns is entirely unlike that of a molecular compound. Patterson and Fourier methods were used to elucidate the structure. It was found that the structure contains tetrahedral $[PBr_4]^+$ groups located so that a plane of symmetry passes through each, and the fifth bromine is present as a bromide ion removed from the phosphorus at a distance about twice that of the four covalently linked atoms. It is natural to expect the stability of the octahedral complex to diminish with increasing radius of the halogen atoms so that the change-over from the constitution $[PCl_4]^+ [PCl_6]^-$ to $[PBr_4]^+ Br^-$ is not surprising.

Formation of Aggregates and Structures in Dilute Solutions of Hydrogen Bentonites

A YIELD value is noticeable in hydrogen bentonites at a concentration lower than that at which thixotropy first appears. This seems to happen generally with bentonites. Some natural calcium bentonites show coacervation[1]. Coacervation of fine subfractions of a natural bentonite has been reported[2] at concentrations above the thixotropic range. Hydrogen bentonites, however, show coacervation over a wide range and even below the thixotropic range of concentrations. Near about the concentration at which yield value becomes noticeable a sharp change in several properties has been observed. The cataphoretic velocity rapidly increases and tends to a maximum. The conductivity, Λ, per gram of colloid can be calculated from the relation $\Lambda = 1000 (\lambda_c - \lambda_u)/C$, where λ_c is the specific conductivity at a concentration of C grams per litre and λ_u that of its ultra-filtrate; it passes through a minimum if plotted against C or $\sqrt{C}$.

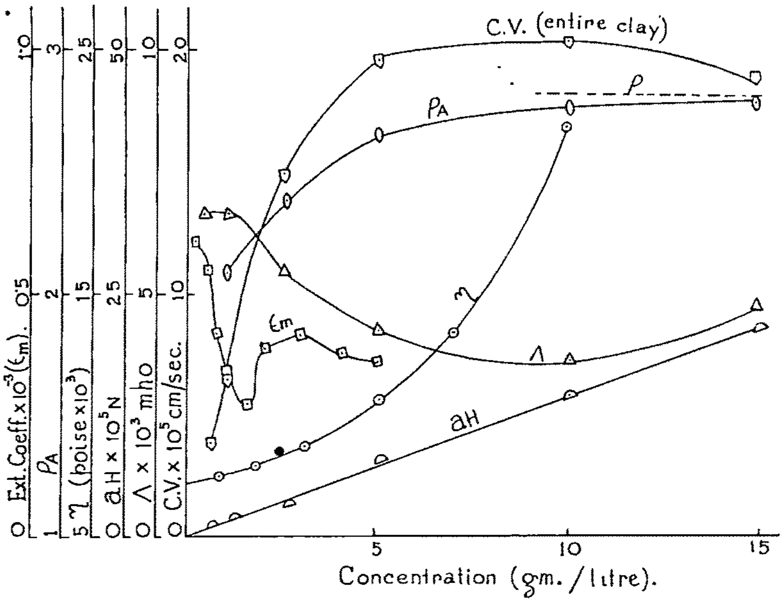
Aggregation during coagulation is often associated with an increase in the cataphoretic velocity[3]. Also the mobility of 'monomeric ions' of 'colloidal electrolytes' has been found to increase when they associate to form 'micelle ions' and pass through a maximum, whereas the equivalent conductivity of the electrolyte as a whole passes through a minimum[4]. The hydrogen ion activity of hydrogen bentonite changes almost proportionally with concentration. The total acidity calculated from the inflexion point[5] in the sodium hydroxide titration curve does not generally vary with concentration, though a variation has been observed for one subfraction of a hydrogen bentonite[6].

The conductivities per gram of colloid calculated from the relation $\Lambda' = a_H (l_H + l_{\text{coll}})/C$, where l_H and l_{coll} are the mobilities of hydrogen and 'colloid' ion respectively, are appreciably greater than Λ. The free charge per particle calculated from a_H, assuming the activity coefficient to be unity, is of the order of 500 or 1,000 electron units. Onsager's conductivity equation[7] for a similar electrolyte in true solution is inadequate to explain the form of the Λ, $\sqrt{C}$ curve.

The special features of these titration curves[5] and the discrepancy between observed and calculated conductivities per gram colloid are, however, met with in hydrogen clays and other similar colloidal systems[8] but are not of immediate interest. The sols have strong absorption. Interpretation of the measurements of extinction coefficient is difficult. The latter decreases with the concentration and passes through a minimum. Somewhat similar changes have been observed with colloidal dyes[9] and ascribed to aggregate formation. The 'true viscosity' increases with C at a rate much greater than that corresponding to a linear relationship.

Neither Einstein's equation nor Smoluchowski's modification of it can account for the high viscosity or its variation with concentration. Also the high viscosity cannot be fully accounted for by the anisometry of the particles. Hauser and LeBeau[10] observed that the apparent specific gravity, ρA, of subfractions of a natural bentonite increases with concentration and approaches a limiting value. However, ρA observed by them in the most dilute solutions is definitely less than the true specific gravity, ρ, of bentonites recorded in the literature, while ρ*A* for the higher concentrations has a definitely larger value and is also greater the finer the subfraction. Hydration cannot explain how ρ*A* can fall below ρ. We find that the limiting value of ρ*A* shows a fair agreement with the specific gravity of the material dried at 110° C. and immersed in toluene.

Air-dried hydrogen bentonite *en masse* has been observed to have the same specific gravity[11] in both water (2·248) and toluene (2·249). The diminution of density and not an increase requires an explanation. The precise manner in which this takes place has to be clarified by further experiments. However, clay minerals of the montmorillonite group show strong swelling in water as a result of the penetration of water molecules into the lattice. If the resulting free space in the lattice is not completely filled by water molecules the apparent specific gravity of the particles will decrease. It appears that with increase of concentration aggregates are first formed and then some sort of a structure develops and a yield value results.



Thixotropy comes next. Coacervation shows itself generally after the development of the yield value but may appear before or after thixotropy develops. Results of measurements obtained with a particular subfraction of a hydrogen bentonite (average effective radius about 12·5–25 mμ) are shown in the figure.

These investigations have been carried out with the aid of a grant from the Assam Oil Co., Ltd.

Total Energy Absorption in Biological Objects

THE total energy absorbed in a biological system when irradiated by a beam of X- or gamma-rays is a quantity of both theoretical and practical interest. The letter by Dr. Happey[1] indicates one method of attempting to solve such a problem, but it seems that the matter may be carried much further. When a beam of X- or gamma-rays is sent into a scattering medium such as a block of tissues, the distribution of radiation absorbed within the tissues may be conveniently represented by constructing 'isodose surfaces'. During the last two years we have carefully studied these surfaces, and they seem to afford the best method of attacking the total energy absorption problem. If the isodose surfaces have an axis of rotation, the volume of tissue between any two surfaces representing given dosage levels may readily be determined, so that by multiplication of volume (or more accurately mass of substance) and average dose we obtain the 'integral dose'. In this way we have studied the integral dose over a wide range of clinical conditions. An indication of the kind of results obtained is given in the accompanying table. The most striking feature is the very large variation in integral dose (always taken to the 10 per cent isodose surface) which exists between the different techniques. The results may be correlated with the very varying constitutional effects produced in the patients by the treatments.

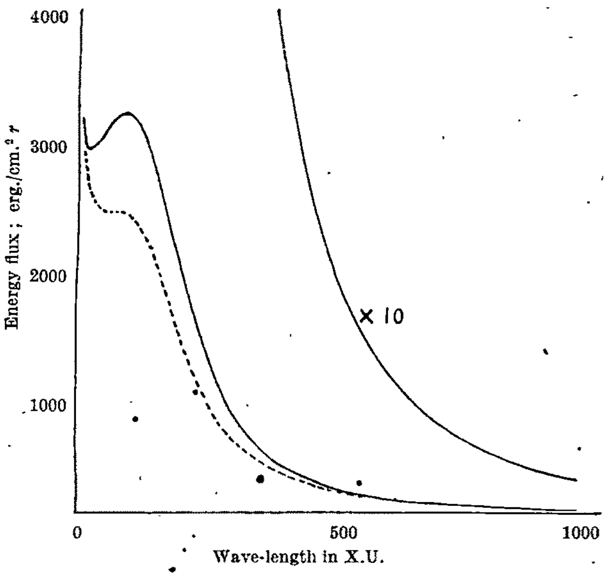
We have also developed semi-empirical formulæ very similar to those of Happey and compared the results of such calculations with the more elaborate isodose surface investigations. The table shows that although there is fair agreement between the two methods there are occasionally wide divergencies.

The problem may, however, be attacked from a third, and perhaps more interesting, point of view. From the definition of the röntgen and the known absorption coefficients of air, it is possible to calculate the total energy flux per cm.^{2} per röntgen for different wave-lengths. The results are shown in the accompanying figure. We may, therefore, calculate the total energy which flows through the surface of the body during a radiation treatment. Many examples of these energy fluxes have been investigated by us, but to fix the order of magnitude we may state that for short wave-lengths ($\lambda = 0{\cdot}01$ A. to $\lambda = 0{\cdot}1$ A.) about half a gm. cal./cm.^{2} is absorbed for the normal therapeutic dose of 6,000 *r* on the skin. It may also be shown that when one röntgen is absorbed in one gram of air approximately 85 ergs are converted into energy of electronic motion. The amount of energy converted per electron per röntgen in other materials likely to occur in living tissues has been recently investigated[2]. We may, therefore, approximately convert the integral doses into total energy absorbed in ergs and compare the results obtained with the energy flux into the body. In this way we usually find that only about one third to one half of the energy poured in reappears as absorption in the

No. of radiation	Type of radiation	Type of technique	Potential in kv.	Filter	Mean wave-length (A.)	Focal distance	Diam. of field	Gram-röntgens to 10% contour	Integral dose from formulæ
1	X-rays	'Röntgen cautery'	45	Unfiltered. Tube only	0·90	2·0 cm.	1·0 cm.	71·5	68
2	X-rays	'Contact therapy'	60	Tube only. 0·2 mm. Ni equiv.	0·33	5·0 cm.	4·0 cm.	4,200	4,950
3	X-rays	'Deep therapy'	200	1 mm. Cu.	0·12	50 cm.	10·0 cm.	96,560	95,000
4	X-rays	'Super-voltage'	400 (peak)	4 mm. Cu.	0·069	50 cm.	10·0 cm.	110,000	107,000
5	γ-rays	One gm. unit	—	1 mm. Pt equiv.	0·014	5·0 cm.	5·0 cm.	14,593	11,200
6	γ-rays	Five gm. unit	—	1·4 mm. Pt equiv.	0·013	8·2 cm.	8·0 cm.	51,587	48,420

primary beam down to the 10 per cent isodose surface, the rest being scattered outwards or absorbed in parts of the body at low dosage-rates. Preliminary calculations indicate that this result is of a reasonable order of magnitude.

These considerations would also seem to have important consequences in relation to protection problems. For example, the 'tolerance' dose is defined as 0·2 *r* per day, and we may, therefore, calculate approximately the total energy absorption for a person of a definite weight exposed for a year to this dosage-rate. It is found that the order of energy absorption per year for gamma-rays at the tolerance dosage-rate is the same as that for one moderate-sized field (10 cm. diameter) during a course of high-voltage X-ray or gamma-ray therapy giving a surface dose of 3,000 *r*. This result may be taken as a warning or an excellent example of the importance of the 'time factor'. Again, if we consider a very small biological object constructed of approximately air-like material, then the dose in röntgens is an approximate measure of the energy absorbed in it whatever the wave-length. If, however, we consider an object sufficiently large wholly to absorb the energy falling on it, then the curve also represents the total energy absorbed per röntgen per cm.^{2} of surface irradiated by a parallel beam. The energy absorbed per röntgen measured on the surface is now clearly very dependent upon the wave-length, and if there are constitutional effects depending upon the total energy absorbed in the organism, we might expect wave-length dependence.



CONTINUOUS LINE, IN AIR; BROKEN LINE, WITH BACKSCATTER.

It will be seen, for example, that a given dose of gamma-rays would correspond to a very much larger energy absorption throughout the absorbing mass than for the same dose in röntgens of longer wave-length radiations such as scattered X-rays of wave-length 200 X.U. or diagnostic X-rays. Many animals and the human body would appear to be of such a size as to provide conditions intermediate between the two extremes, the magnitude of the effect depending upon the relative size of the absorbing mass and the 'mean free path' of quanta within ($1/\mu$). Owing to the complexity of the circumstances it has not yet been possible to obtain accurate information though we have some data; but it should be realized that there is some physical basis for expecting the tolerance dose to decrease with wave-length. The classical proofs of independence of biological effect with wave-length using very small biological objects would seem to have no necessary validity for large absorbing bodies.

Finally, we have been able to compare the energy flux during normal short wave-length X-ray or gamma radiation treatment with that occurring during ultra-violet light irradiation.

The whole subject has as yet scarcely become quantitative, and much more investigation is required, but it is clear that it offers important problems in biophysics. An account giving details of the physical and mathematical investigations carried out by us during the last few months has been submitted for publication elsewhere[3].

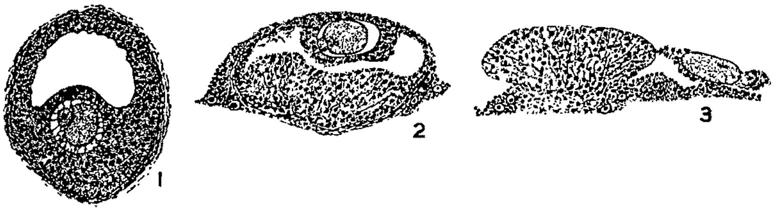
Mechanism of Ovulation and Corpus Luteum Formation in Elephantulus

In the course of an examination of serial sections of close on two hundred uteri and ovaries of *Elephantulus myurus jamesoni* in our studies on the menstrual and reproductive processes of this animal, we have had the opportunity of observing all phases of follicular and luteal growth in the ovary. This was facilitated by the fact that Elephantulus sheds up to sixty ova at a time from each ovary although only one embryo develops in each uterine horn. The corpus luteum does not commence to form *after* the extrusion of the ovum from the follicle, but rather before the ovum is extruded. In fact, the corpus luteum is responsible for ovulation (see accompanying illustration, 3).

The luteinizing granulosa cells proliferate at one pole of the follicle, encroach on the follicular cavity which is gradually obliterated, and the ovum is steadily pushed out of the follicle through the superficial layers of the ovary. During the process the theca interna proliferates, is vascularized and in turn invaginates the heaped-up luteal cells. By this method the original epithelium lining the follicular cavity is everted so that the free margin of the corpus luteum represents anatomically the lining epithelium of the original cavity, which now projects from the surface of the ovary, and the attached portion is vascularized by thecal vessels which extend radially towards the expanded free margin of the newly found corpus luteum.



1, Ripe Graafian follicle; 2, Graafian follicle on the surface of the ovary, preparatory to ovulation; granulosa cells are commencing to luteinize; 3, recently ruptured follicle with attached ovum and everted corpus luteum (×c.80).

Many theories have been invoked to explain the exact mechanism of ovulation, such as the increased tension produced by the secretion of the liquor folliculi, the contractions of smooth muscle and the action of enzymes[1].

While the method of corpus luteum formation in Elephantulus is unique and is so totally different from the accepted procedure in other animals, it nevertheless negates the above-mentioned theories of ovulation.

The findings in Elephantulus substantiate the claims that ovulation is a phase in the growth process controlled by the gonadotropic hormones, since there is most convincing evidence that pre-ovulatory differentiation occurs in the granulosa cells of the follicle.

Possible Relation between Ability to Synthesize Vitamin C and Reaction to Tubercle Bacillus

We had occasion to write the following two lists within a few days of one another and were struck by the close similarity between them :

Classification of Ability of Different Mammalia Species

(A) To synthesize vitamin C (McCollum 1939)[1].	(B) To resist infection with human and bovine tubercle bacillus (M.R.C. 1930)[2].
1. Require vitamin C in their diet (that is, are unable to synthesize vitamin C themselves): Man. Monkey. Guinea pig.	1. Susceptible to infection by both bovine and human tubercle bacillus : Man. Monkey. Guinea pig.
2. Query require vitamin C in their diets (that is, authorities are in doubt as to their ability to synthesize vitamin C) : Rabbit. Pig. Cattle Mouse.	2. Susceptible to bovine but resistant to human tubercle bacillus. Rabbit. Pig. Calf. Goat. Sheep. Horse.
3. Do not require vitamin C in their diet (that is, are known to be able to synthesize vitamin C) Dog. Rat.	3. Resistant to both bovine and human tubercle vacillus : Mouse. Dog. Rat.

We feel that this similarity is too close to be a pure coincidence and that there is possibly a relation, at present obscure, between the ability to synthesize vitamin C and the reaction to the tubercle bacillus. This is especially interesting in view of the number of papers appearing recently which suggest that the vitamin C metabolism is higher than normal in tubercular patients.

Growth of Protoplasm and Nitrogen Migration in the Coleoptile of *Zea Mays*

It is generally accepted that during the growth in length of meristematic plant cells the increase of volume is principally caused by the formation of a big vacuole, whilst the protoplasm does not grow considerably. Investigations[1] on the coleoptile of *Zea Mays* disprove this view. Cytological measurements of the plasmatic content before and after the phenomenon of cell stretching show an increase of protoplasm of 1,670 per cent and more. This cannot be due to a simple swelling of the protoplasm, as during this time the protein nitrogen of the cells increases as many as 9·5 times. Therefore there is not so striking a difference between the behaviour of protoplasm in growing cells of plants and animals as is generally believed.

In the growing coleoptile considerable amounts of water-soluble and protein nitrogen migrate upwards, whilst the auxins migrate downwards. So long as the coleoptile is growing its content of total nitrogen is increasing. Only in the withering coleoptile a decrease of nitrogen does take place. But the coleoptile is not completely emptied of nitrogen before it dries. In this way every germ loses about 2 per cent of the nitrogen originally stored in the seed.

Algæ in the Bed of the Dead Sea

THE presence of living micro-organisms—algæ and bacteria—in Dead Sea water was demonstrated by me some time ago.[1] It seemed, therefore, probable that life was also abundant in the sediment bed of the Dead Sea. To throw light on this point an investigation on a sample of sediment obtained from the sea bottom has been carried out.

The sediment sample was taken by means of a Fischer bottle at a point 23 km. west-south-west of the mouth of the Jordan and *c.* 8 km. off the east coast on December 28, 1939. The depth of the sea at this point is 350 m. The total salt concentration in the water near the sea bottom is 32 per cent. The specific gravity at 20° C. is 1·212. The percentage of different salt species in the sea water is as follows:

$NaCl$	9·42
KCl	1·42
$MgCl_2$	14·41
$CaCl_2$	4·78
Br	0·46

After storage for about three months at room temperature, the sample of sediment was examined microscopically for signs of life. These were abundantly in evidence. So far 17 species of algæ, living and dead, among them 4 or 5 Chlorophyceæ and 12 Diatomeæ, have been detected. The following have been identified:

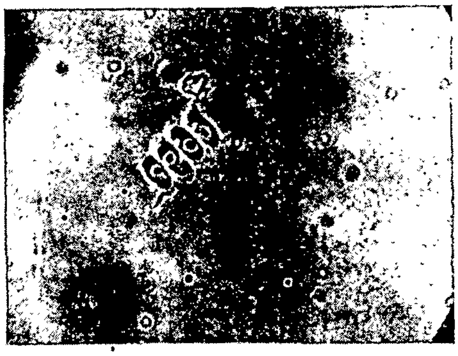

Fig. 1. × 900.

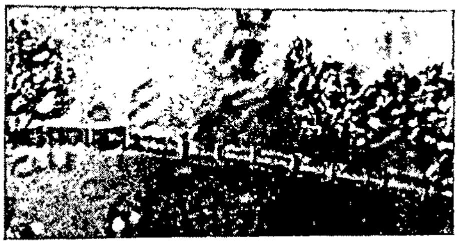

Fig. 2. × 900.

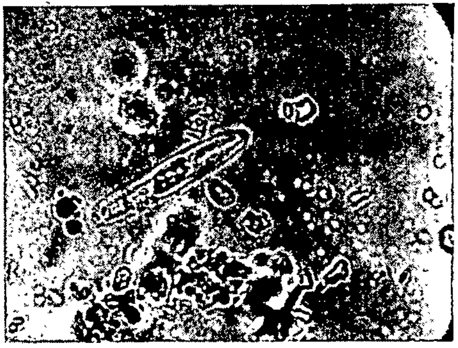

Fig. 3. × 900.

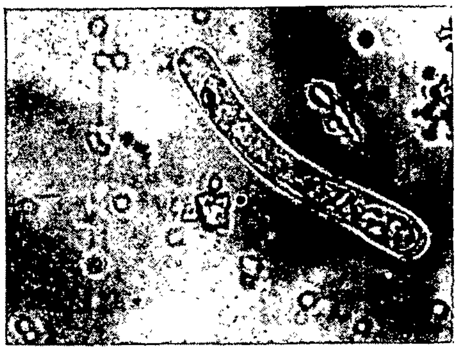

Fig. 4. × 900.

Chlorophyceæ: (1) *Scenedesmus quadricauda* (Fig. 1); (2) a filamentous alga of the order Ulothrichales (Fig. 2).

Diatomeæ: (1) Pennatæ, including Naviculoideæ (Fig. 3); (2) Centricæ, including Melosira.

A species of Chlorophyceæ most commonly observed was of an elongated type with a greenish-yellow chromatophore, occasionally seen in pairs (Fig. 4). In several diatoms the chromatophore was visible. It seems likely, therefore, that the diatoms found in the sea bed are at least in part alive.

A full description of the Dead Sea bed algæ will be published elsewhere.

Thanks are due to the Palestine Potash, Ltd., for submitting the sample and the water analysis.

Comparative Morphology and Evolutionary Trends in Trichoptera

THE internal anatomy of adult Trichoptera has been very little studied, especially on a comparative basis. A detailed attempt has been made in this direction and some interesting results have been obtained. In a study of the internal anatomy of six families of adult Trichoptera, the following significant conclusions have been drawn.

(1) There is a correlation between the structure of the systems and the habitat. It seems that the modification of Trichoptera has been associated with the invasion of poorly aerated waters as exemplified by the swift (flowing) stream-inhabiting *Rhyacophila dorsalis*, and slow stream-inhabiting *Mystacides longicornis*.

(2) Different systems in the same species do not evolve synchronously ; that is to say, there has been a differential intra-organic evolution.

(3) The trend of evolutionary development in adult Trichoptera has been towards reduction and simplification of structure, associated with a tendency towards non-feeding in the adult and the shortening of life.

It is hoped that the above results will shortly be published in detail.

Effect of the Severe Winter of 1939-40 on British Oyster Beds

PROF. ORTON has recently recorded[1] some details of the damage caused by the severe winter just past on the oyster beds of the Rivers Blackwater and Roach. As the result of an inspection of these and other beds during the period April 9–19, I am able to supplement the information given by him.

There is no doubt that the entire stocks of Brittany oysters (*Ostrea edulis*) relaid in the Blackwater and Roach Rivers have been destroyed. During a day's dredging on the River Roach no living Brittany oyster was found, while of the one or two per cent remaining alive in the Blackwater at the time of the survey nearly all were weak and contained mud in the mantle cavity, despite the fact that the water temperature had risen to 7·5° C. during the period between the surveys conducted by Orton and myself.

Oysters from Brittany are relaid at two other points on the East coast, namely, in the River Medway (Hoo Creek) and off Whitstable. In the Medway the mortality was 100 per cent. At Whitstable the mortality among Brittany relaid oysters was about 95 per cent and the survivors were still weak.

Brittany oysters relaid in the River Yealm, South Devon, have not suffered to the same extent, the mortality not exceeding 30 per cent, while in the Helford River, Cornwall, the losses were only slight.

Among native oysters the losses have not been so high, although the figures obtained in April were considerably higher than those recorded by Orton, showing that the losses had continued, as he had anticipated. In the Blackwater, 75–80 per cent of the native stocks have been destroyed, while in the River Roach 80 per cent of these oysters have died. In the River Colne and in Pyefleet the mortality among the stock of natives is estimated at 75 per cent and it is noticeable that here, as elsewhere, the larger oysters have suffered most severely. The survivors were still weak at the time of the survey. On the layings in the various creeks at West Mersea the mortality was somewhat variable, depending upon the amount of protection from silt driven in by easterly winds, but was nowhere less than about 50 per cent and reached 75 per cent or rather more in places.

In the River Crouch, which probably carried a larger stock of native oysters than any other river in the country, conditions were slightly better and the mortality did not exceed 50 per cent except in the upper reaches of the river. Of about a million oysters which had been collected in the storage pits when the frost set in, nearly 50 per cent have died and the survival of the remainder is doubtful.

At Whitstable native oysters have survived in considerable numbers, particularly those bred on the Whitstable Flats, and although precise figures are not yet available the mortality is not expected to reach 50 per cent. The losses among native oysters in Cornwall were slight, but the stocks were not high.

American oysters (*Ostrea virginica*) are laid down in the creeks at Brightlingsea and West Mersea, and by Christmas the stocks remaining on the layings were small ; the losses experienced vary between 25 and 50 per cent. Portuguese oysters (*Ostrea angulata*) are laid down at Brightlingsea, West Mersea and in the River Medway. The mortality varies somewhat from creek to creek. Estimates of the losses vary from 35 to 50 per cent.

Oysters bred on tiles in the experiment tanks at Conway, North Wales[2], and planted out in the Menai Straits, in situations where they are uncovered at spring tides, have suffered very little loss, despite several weeks of severe frost, and air temperatures down to −12° C. Similar tank-bred oysters in the River Yealm, South Devon, have also survived the winter without serious losses.

During the course of the survey of East coast oyster beds no evidence was found of any mortality among the slipper limpets (*Crepidula fornicata*) infesting these beds, other than a report of considerable deaths in the very shallow waters of Hoo Creek, River Medway. Elsewhere the clumps of slipper limpets were all tightly joined and no recently emptied shells were obtained in the dredge. The general weakness noted by Orton was nowhere apparent.

Recent samples of *Urosalpinx cinerea*, the American oyster drill, from the East coast beds contain only an occasional empty shell and show definitely that this pest has once again survived a severe winter without loss[3]. No living specimens of *Ocinebra* (*Murex*) *erinacea*, the British drill, have been noted in recent samples of drills from the River Blackwater, as contrasted with approximately 9 per cent in similar samples collected a year ago. It appears as if Urosalpinx has now almost completely replaced Ocinebra on the East coast beds.

Effect of X-Rays on Carboxypeptidase

In a recent review[1] of the biological action of X- and gamma-rays, the conclusion is reached that only enormous doses of X-rays have an appreciable destructive effect on enzymes and that enzymes therefore play no important part in explaining the effect of X-rays on living tissues.

I have examined the effect of X-rays on crystallized carboxypeptidase[2] (substrate : edestine) with the following results.

The percentage destruction is a function of the concentration of the enzyme for a given dose of radiation. A definite amount of radiation energy absorbed corresponds to a constant amount of enzyme destroyed. In consequence, the percentage destruction increases as the concentration of the enzyme decreases : for example, if the concentration of the enzyme is 0·0080 $(\text{C.P.u})^{\text{PDE}}$ per ml., 50,000 r. will destroy 21 per cent, 150,000 r. 50 per cent and 400,000 r. 65 per cent. However, if the concentration is 340 times lower, then 50 r. will destroy 29 per cent, 140 r. 50 per cent and 400 r. 70 per cent.

This shows that the concentration of enzymes has to be taken into account if statements regarding their radio-sensitivity are made. It shows, furthermore, that X-rays have a qualitatively uniform effect on the enzyme over the whole range of doses, from very small doses to doses a thousand times as large. This point is of importance in view of the opinion held by many that small doses act in an essentially different way from big doses.

Finally, I have found that X-rays have no effect at all on the enzyme carboxypeptidase when it is combined with its substrate during irradiation, whereas the enzyme simultaneously irradiated without its substrate showed 85 per cent destruction.

Details of the work will be published elsewhere.

"Books in War-Time"[1]

In the libraries books are divided into two great classes : fiction and non-fiction. Nine tenths of the fiction published is of such poor quality that it could well be spared in war-time, whereas publications on non-fiction nearly always contain something of value. Good fiction is valuable and should not be discouraged, but a reduction of the present enormous volume of bad novels would give the few good ones a better chance of recognition. The Government might therefore consider whether the allotment of paper for fiction might not be cut by 90 per cent whilst allowing full supplies for non-fiction, which would be sufficiently handicapped by rising prices.

Points from Foregoing Letters

S. E. Sheppard, R. H. Lambert and R. D. Walker find the necessary and sufficient conditions for optical sensitizing of silver halides by dyes to be : (1) planar configuration of dye molecule ; (2) edge-on adsorption of dye ion or dipole ; molecular plane orthogonal to a (110) plane of silver-halide crystal ; (3) electronic transition in dye ion or molecule on absorption of light polarized in azimuth, defined by (1) and (2).

A new apparatus has been used by R. S. Vincent for measurements on the cohesion of liquids. A metallic bellows is employed for applying tension to the liquids, and it has been found that the maximum tension which can be applied is simply related to surface tension and vapour pressure, and that the effect of temperature can be largely explained by the changes in these properties.

H. M. Powell and D. Clark show that phosphorus pentabromide has a crystal structure entirely different from the pentachloride. A constitution analogous to $[\text{PCl}_4]^+$ $[\text{PCl}_6]^-$ is no longer stable owing to the larger radius of the bromine but an ionic structure is formed containing $[\text{PBr}_4]^+$ and Br^- ions.

A study by J. N. Mukherjee and N. C. Sen Gupta of the variation of several properties of dilute solutions of hydrogen bentonites with concentration suggests that aggregate formation in bentonites begins at a very low concentration. At a somewhat higher concentration these aggregates form some sort of a structure and a yield value develops.

The total energy absorption of biological objects subjected to X- or gamma-rays has been investigated by the construction of 'isodose surfaces' for the tissue. W. V. Mayneord describes results that have been obtained.

B. Elazari-Volcani reports that he has found seventeen species of algæ in material obtained from sediment from the bottom of the Dead Sea. Photomicrographs are submitted.

P. J. Deoras, working on the internal anatomy of six families of adult Trichoptera, finds that the trend of evolutionary development has been towards reduction and simplification of structure associated with a tendency towards non-feeding in the adult and the shortening of life. Further, there has been a marked differential intra-organic evolution.

As the result of a survey of the damage caused by the severe winter just passed on British oyster beds, H. A. Cole has found that virtually the entire stocks of Brittany relaid oysters (*Ostrea edulis*) on the Essex and Kent beds, probably amounting to thirty millions all told, have been destroyed, while the stocks of native oysters have been reduced by about 75 per cent.

W. M. Dale has exposed solutions of the crystalline enzyme carboxypeptidase to X-radiation. He finds that the percentage destruction of the enzyme is a function of its concentration, increasing as the concentration decreases.

RESEARCH ITEMS

Teeth of Finnish Lapps

A DISCUSSION by Helen Mellanby (*Brit. Med. J.*, April 27, 1940) of dental deformation and caries among Finnish Lapps, and their relation to changes which have taken place in the national diet, is based upon observation of 1,253 teeth of seventy children between two and fourteen years of age, undertaken in June 1939. The teeth are charted for hypoplasia and caries. The teeth of both Inari and Skoltje Lapp children are of very imperfect structure. Only 25 per cent of the deciduous teeth, and in the permanent teeth only 6·7 per cent, were of good or normal structure; and even these figures may be too high in view of allowances for attrition. As might be anticipated from the poorness of structure, caries is rampant. All children over four years of age were affected, and out of the total of seventy only three were caries-free. Of deciduous teeth 55·3 per cent and of permanent teeth 44·5 per cent were carious. Among Eskimos of East Greenland, only 2–4 per cent of the deciduous teeth and 1–1·4 per cent of the permanent teeth in the ages 0–13 years were affected. In the cranial material, only a proportion of the teeth remained. Nevertheless, comparative examination shows a decided deterioration in structure and increase in carious affection in the modern material. There is evidence to suggest that deterioration set in about 1900 when Finns began to immigrate in numbers. Further, in the last century or more the diet of the Lapps has changed. Like that of the 'uncivilized' Eskimos, it was almost entirely carnivorous, a low calcium intake being made good by chewing bones. In the modern dietary there are important differences, notably cheap margarine, coffee, oatmeal, sugar and potatoes. Cereals are consumed in large quantities during the winter. If allowance is made for the anti-calcifying effect of a high cereal content of the diet, it may account for a deterioration in tooth structure which is correlated with a greater liability to caries.

Fishes of the John Murray Expedition

A MAGNIFICENT collection of fishes is described by J. R. Norman (John Murray Expedition 1933–34. *Sci. Rep.*, **17**, No. 1. Fishes. British Museum (Natural History), 1939). These were obtained from the Red Sea, Gulf of Aden, South Arabian coast, Gulf of Oman, Arabian Sea and in the Zanzibar and Maldive areas, chiefly from regions largely unexplored for deeper water fishes, and, as was to be expected, there are many which are new to science (28) and new to the British Museum collection (56). 276 species are represented altogether. Some of these deep-water species from the Zanzibar region and the Gulf of Aden were hitherto only known from the Philippines and adjacent seas, but the author is convinced that more extensive collecting in the intervening areas of the Indian Ocean would show that most of these forms have a wide range in this part of the world. Among the interesting finds is an egg capsule from the depth of 1,061–1,080 metres, of one of the Chimæridæ, probably Harriotta. A synopsis of the Oceanic genera of the Brotulidæ is included in the report and a key to these.

Biology of Rubus Aphides

G. H. L. DICKER (*J. Pom. and Hort. Sci.*, **18**, 1; 1940) has carried out a detailed investigation into the biology and morphology of four important pests of Rubus, *Macrosiphum rubiellum* Theo., *M. rubifolium* Theo., *Amphorophora rubi* (Kalt) and *Aphis idæi* van der Goot. Field observations were made to elucidate the life-histories, and statistical data obtained on seasonal fluctuations of the populations. It appears that Coccinelid larvæ are responsible for the decline in populations during August. A comprehensive list of host plants is given for each of the common aphides, and consideration of their origin shows that there is often a close correlation between the genetical constitution of the host and the species of aphides breeding on it. Thus, *M. rubiellum* shows definite preference for species of blackberry or blackberry crosses, whilst the raspberry and its hybrids are avoided. This selectivity narrows down the field of investigation of virus diseases transmitted by aphides. Notes are given on six other species of aphides recorded on Rubus in Great Britain, and one unnamed species related to *Aphis Urticaria* Kalt.

Spores of Bryophyta

Miss Knox has added to her experience of spore types by a survey of Bryophyte spores (*Trans. and Proc. Bot. Soc., Edin.*, **32**; 1939), with the view of identifying fossil spores in coal. The survey shows great variety among liverwort spores, as compared with considerable uniformity among those of mosses. The liverwort spores have a wide range in size and also in the type of wall sculpturing, and this is especially striking in the case of certain genera which are also characterized by other features of form and structure, such as Frullania. Evidence from various sources suggests that Bryophyta had reached a considerable degree of specialization by Carboniferous times, and it is probable that many of the spores found in the Fife coals may be of this origin. Though the author would not suggest that specific or even generic significance should be attached to them, the broad comparisons of spore types suggest that many of the living groups of Bryophyta were represented at that time. Certain characteristic spore forms, such as those of Frullania, Mastigolejeunia, Grimaldia, Targionia, and, among mosses, Breutelia, have not been recognized from the coals, whilst types closely resembling species of Anthoceros, Riccia, Moerkia and Fossombronia are present.

A Rhododendron Complex

THE beautiful *Rhododendron sanguineum*, regarded as a single species at the beginning of this century, has now become a taxonomic incubus of very numerous, intergrading forms. Activities of plant collectors in western China have contributed greatly to horticultural beauty, but have added to the difficulties of the plant systematist. John M. Cowan, in a most useful evaluation of the Sanguineum subseries (*Notes Roy. Bot. Gard. Edin.*, **20**, No. 97, pp. 55–91; February 1940), has shown that there are eight recognizable species, comprising 43 sub-species, in the group. The key and descriptions which are given should provide an adequate taxonomic framework, and should bring order to this formerly chaotic section of botanical classification. Considerable restraint has been practised by the author to avoid unpractical 'splitting', and his conclusions are based upon the examination of several thousand living plants and herbarium specimens.

Position of Chiasmata

K. Mather (*J. Genetics*, 39, 205–223; 1940) has continued his studies on the determination of the position of crossing-over. The ratio of differential-interference-distances, that is, the distance between the centromere and the proximal chiasma and between the proximal and second chiasma may be used to describe the distribution of the chiasmata on the chromosome. Analysis of the cytological results in several species shows that the agreement between this ratio and the observed positions of chiasmata at metaphase and anaphase is close. Therefore the author suggests that the position of chiasmata at metaphase is the same as at chiasma formation; terminalization is an all or none process. Either all chiasmata terminalize or only the most distal ones move to the ends without reducing the frequency of chiasmata. This hypothesis therefore implies that chiasmata (*a*) tend to have determinate positions, and (*b*) no detectable change in these positions occurs after formation, unless potentially complete terminalization is also present.

Incompatibility in Cosmos

T. M. Little, J. H. Kantor and B. A. Robinson (*Genetics*, 25, 150–156; 1940) show that *Cosmos bifurcatus* is completely self-sterile. As the result of intercrossing 25 plants they have found three intrasterile interfertile groups with indications of two further groups. The behaviour is accounted for on East's hypothesis of incompatibility factors. The genetic constitution of the three groups is s_1s_3, s_1s_2, s_2s_3, while a further group contains s_4.

Pollination in Maize

Mangelsdorf had found that a gene sp_1 gives rise to small pollen grains. Only about 1 per cent of these achieve fertilization in competition with normal-sized pollen grains, but are fully functional when the normal pollen is eliminated by screening through sieves. W. R. Singleton (*Proc. Nat. Acad. Sci.*, 26, 102–104; 1940) found that when the maize strains Purdue 39 and Connecticut 81 were crossed with heterozygous $\mathrm{SuSp}_1/\mathrm{susp}_1$ plants, 39 per cent and 17 per cent *su* seeds were produced although the cross-over percentage between *su* and sp_1 is 6. Further breeding confirmed that in these crosses the small pollen grains carrying sp_1 had functioned. The inbred strains Purdue 39 and Connecticut 81 have greatly increased the functioning of the small pollen grains. The reasons are unknown.

Earthquakes of Missouri

Ross R. Heinrich has examined lists of earthquakes of Missouri and states that most of these earthquakes originate in more or less definite seismic districts (*Trans. Amer. Geophys. Union*, 1938). Six such districts are suggested for Missouri; they are the New Madrid, St. Mary's, St. Louis, Hannibal, Springfield, and north-west Missouri seismic districts. Some of the earthquakes which have been felt in Missouri have apparently originated in seismic areas outside the State boundaries. Four such are the Centralia and Harrisburg districts in Illinois, the Anna district in Ohio, and the Kansas-Nebraska Nemaha Belt. About 85 per cent of all the seismicity of Missouri origin comes from two seismic areas; about 60 per cent from the New Madrid area, and about 25 per cent from the St. Mary's Fault Region. A tabulation of the earthquakes by intensities indicates that most of the activity of strong intensities also seems to originate in the south-eastern Missouri area, although only about 7½ per cent of the total earthquakes recorded since the New Madrid series have been strong enough to endanger life.

Ionization Constants of Weak Acids

A new method of calculating ionization constants of weak acids from conductance (Λ) measurements (B. Saxton and L. S. Darken, *J. Amer. Chem. Soc.*, 62, 846; 1940) depends on the following procedure. The degree of dissociation is $\alpha = \Lambda/\Lambda_\infty$, where Λ_∞ = conductance of completely dissociated acid at the same ionic concentration. Then $k = \alpha^2 c/(1-\alpha) = c_i^2/c_u$, where k is the mass action constant, c is total concentration, c_i and c_u are ionic concentration and concentration of undissociated acid. Now $\gamma^2 k = K$, where γ is mean ionic activity coefficient and K is thermodynamic equilibrium constant. The Debye–Hückel equation gives $\log \gamma = -A\sqrt{c_i}$, where A is a constant. Hence $\log K = \log k - 2A\sqrt{c_i}$. K is found by extrapolating to infinite dilution a plot of $\log k - 2A\sqrt{c_i}$ against c_u, this being found empirically to be linear up to a concentration of almost 1 *m*. The values of K at 25° for cyanoacetic, formic and butyric acids are calculated.

Reality of Periodicities

The controversy as to the reality of the periodicities found by Fourier analysis of the observations of the solar constant (Abbot, *Smithsonian Misc. Coll.*, 94, No. 10, 1935; Paranjpe, *Quart. J. Roy. Met. Soc.*, 64, 459, 1938; Sterne, *Proc. Nat. Acad. Sci.*, 25, 559, 1939) has been carried a stage further by Dr. H. R. Hulme (*Observatory*, 63, 101; 1940), who approaches the subject from the statistical point of view. Hulme develops a test which, when applied to the amplitudes found for the periodicities, decides whether or not they are small enough to have arisen from statistical fluctuations. He points out that care must be taken that the observations are independent in the sense that the value of any one is unconnected with the values of neighbouring ones; this is conspicuously not the case with the 10-day means published by Abbot. It is found that random fluctuations active for a time comparable with a quarter of the length of the period in question are quite capable of producing illusory periodicities of the amplitudes actually found by Abbot for all his periodic variations. Sterne's method of assessing the reality of the periodicities by calculating the probable errors of their amplitudes also requires independence amongst the observations for its correct application; and Hulme regards his results as indicating not that the periodicities are real but that the fluctuations persist over a number of 10-day intervals. This is physically quite understandable, and such effects can evidently produce 'periodicities' of the observed order of magnitude. It is concluded that the periodicities should not be regarded as real until the more stringent test of successful prediction has been passed.

THE ROYAL OBSERVATORY, GREENWICH

ANNUAL REPORT OF THE ASTRONOMER ROYAL

THE annual report of the work of the Royal Observatory, Greenwich for the year ending May 1, 1940, was presented by the Astronomer Royal to the Board of Visitors on June 1. The following are among the chief items of the report.

Reversible Transit Circle. The observations for providing the foundations of a system of right ascensions have been continued. More than 3,500 transits were observed during the year besides a large number of observations for determining the collimation, level and azimuth of the instrument. The level error has proved to be subject to rapid diurnal variations due to changes of temperature and direction of wind. Experiments are being made to reduce these fluctuations to a minimum. Observations for the errors of the divisions of the fixed circle are progressing; already to date some 180,000 individual microscope readings have been made.

Small Transit Instrument. A small reversible transit instrument made by Cooke, Troughton and Simms has been purchased from the Crown Agents for the Colonies. The instrument is of more modern design than the small transit instruments made in 1874 hitherto in use at the Observatory for time determinations. It is hoped that observations made on the same night with (1) the new instrument, (2) the small transit in current use, (3) the large reversible transit circle, will give useful information concerning fluctuating errors of instrumental origin.

Total Eclipse of the Sun on October 1, 1940. An expedition from Great Britain had been planned to observe this eclipse in South Africa. On the outbreak of war, the plans for the Royal Observatory expedition were cancelled, but a part of the equipment, together with spectrographic instruments from the Solar Physics Observatory, Cambridge, has been sent to South Africa for use by a combined expedition from the Royal Observatory, Cape of Good Hope, and the Union Observatory, Johannesburg.

The Greenwich Equatorials. (*a*) 28-inch refractor, (*b*) 26-inch refractor, (*c*) 36-inch reflector (Yapp). Work on both (*a*) and (*b*) ceased on September 1–2, when the object glasses of the instruments were dismounted for safety. Up to that date, however, 402 plates suitable for parallax measurements had been taken with (*b*). Work with the slit-spectrograph on the Yapp reflector has been continued, and 49 ultra-violet spectra of 35 *F* to *M*-type giant stars have been obtained to test the possibility of the presence of high-temperature companions to those stars that are spectroscopic binaries.

Observations of Eros. The discussion of the material obtained at the 1931 opposition already to hand is in progress. It is clear that the final value of the solar parallax will be nearer 8·79″ than 8·80″, the latter value being that adopted in the *Nautical Almanac* and other natural ephemerides.

Solar Observations. The downward trend of the present 11-year cycle after a very high maximum in 1937–38 seems now established, although the sun has shown considerable activity throughout the year. Three of the numerous groups of sunspots recorded equalled or exceeded 2,000 millionths of the sun's hemisphere at their maximum development. The relationship between bright chromospheric eruptions and magnetic storms has been studied at Greenwich during the past year.

Time Service. Astronomical determinations of time were made on 121 nights with the small reversible transit. Star places based on the FK3 Catalogue have been used in the reductions since January 1. The universal adoption for the time determinations of the same fundamental system of star places will make the times determined at different observatories more directly comparable than hitherto. The principle of employing a 'mean clock' has been continued. Six Shortt clocks normally comprise this mean clock.

The quartz crystal controlled oscillator clock is running satisfactorily, but with rather a large rate, and the performance is not as good as it should be. At the completion of the present run, it may be necessary to have a fresh crystal cut; and the opportunity will be taken to use a fundamental frequency of 100 kilocycles per mean solar second instead of per mean sidereal second as at present. The usual service of rhythmic time signals radiated by the Post Office has been maintained. For about two months short-wave transmission was used. The B.B.C. six dots and hourly signals for controlling the 'talking clock' have also been transmitted regularly.

Nautical Almanac Office. The work of the Office has been mainly devoted to the routine calculation and proof reading involved in the preparation and publication of (1) the *Nautical Almanac,* (2) the *Abridged Nautical Almanac,* (3) the *Air Almanac,* (4) the *Astronomical Navigation Tables,* and for the first year (5) the *Apparent Places of Fundamental Stars.* Surveying this large output of material, the report adds that the Office is now responsible annually for the calculation and publication of about 5,500 large octavo pages of figures; there is probably no other institution of similar size that approaches this output.

Magnetic and Meteorological Observations. The variations of declination, horizontal force and vertical force have been continuously recorded photographically throughout the year at Abinger, absolute observations being made every weekday. The La Cour magnetographs installed during 1937–38 continue to give very satisfactory results. During the year, 30 magnetic storms were recorded of which 7 were 'great' storms. The disturbance on March 24 ranks among the greatest storms of the past ninety years.

Routine meteorology was commenced at Greenwich on November 9, 1840, and the Meteorological Department has thus now entered the hundredth year of its existence. The mean temperature for the past year was 49·1° F. (0·4° lower than the average of seventy-five years, 1841–1915). The highest temperature in the shade was 85·2° on June 7; the lowest, 12·4°, on January 20. Temperatures of freezing point or below were recorded on 66 days, of which 27 were in January. The total rainfall was 30·23 inches, which is 5·99 inches greater than the average.

The Astronomer Royal concluded his report as follows:

"In last year's Report, reference was made to the deterioration of the conditions for astronomical observations at Greenwich and for the urgent need for the Observatory to be removed to a site where the conditions are favourable. At the same time the increasing magnetic disturbance at Abinger caused by the development of electric traction requires the removal of the magnetic observations to a site remote from railways, if high precision in the observations is to be attained and if the Observatory is to be secure for the future against further developments in railway electrification. A number of possible sites, both for the astronomical and for the magnetic observations, were examined during the year. The further consideration of the plans for the removal to new sites of the astronomical and magnetic observations has necessarily had to be deferred until after the conclusion of the War.

"The further improvement in accuracy of the time service provided by the Observatory has been under consideration. For purposes where high precision is needed, corrections to the time signals are published at approximately monthly intervals, after the errors of the mean clock have been satisfactorily determined from a large number of observations. The great developments in recent years in precision frequency standards and in their use have created a need, which is extending rapidly, for time signals of such precision that an interval of 24 hours can be measured to an accuracy of one thousandth of a second, without the application of corrections published after a considerable interval. This precision is not attainable with pendulum clocks, which are less accurate than the precision frequency standards themselves. The installation of a battery of quartz crystal oscillator clocks of the highest precision is required, in order that the frequency stability of modern frequency standards may be satisfactorily controlled. Conferences on this subject have been held with the Radio Section of the General Post Office and the Research Department of the British Broadcasting Corporation. The help and collaboration of these bodies and also of the National Physical Laboratory are greatly appreciated and should go far towards enabling a satisfactory scheme to be drawn up."

THE PHYLOGENY OF MAN

PROF. W. E. LE GROS CLARK, discussing recent additions to evidence bearing on the phylogeny of man (*Biol. Reviews*, 15, 2, 1940), begins by passing in review the fossil man-like apes, commencing with the Eocene Tarsioids and the Anthropoidea, of which the earliest representative is Parapithecus from the Oligocene of Egypt. It has now become evident that at the beginning of the Miocene the main groups of the anthropoid apes which exist to-day were already undergoing separately their evolutionary definition. It is probable that the human line of descent became first differentiated at this period and that the initial appearance of the Hominidæ is to be sought in the palæontological records of this period.

The evidence for the fossil man-like apes, the Dryopithecidæ, though widespread, consists almost entirely of teeth. Nevertheless, it points to the existence of some twenty to thirty different species, indicating that differentiation from generalized ancestors had already begun. Some of these species already show marked resemblance in dentition to man, while others approximate to the orang. In the Brahmapithecus and Ramapithecus discovered in India the resemblance to man is even more emphatically marked—so much so, indeed, that question has been raised as to the propriety of including Ramapithecus in the Simiidæ rather than the Hominidæ. A comparison with the Pleistocene apes of South Africa, of which portions of the skull are available, leaves no doubt as to their Simian status.

The evidence relating to the Miocene apes, then, suggests that they may have included among their number the direct ancestry of man. The only evidence apart from teeth, relating to the Dryopithecine groups, consists of a femur and shaft of a humerus of somewhat uncertain identification. If as is probable they are to be accepted as belonging to Dryopithecus they suggest that Dryopithecus was a 'ground-ape'; and there is every reason to believe that the human line took its origin from a form adapted to a terrestrial life.

Of the extinct man-like fossil apes of South Africa, while there can be no reasonable doubt of the human characters of the milk dentition and palate of Australopithecus, the main difficulty of interpretation lies in the attempt to assess the characters of the adult from an immature individual. Of the recently discovered Paranthropus and Plesianthropus of R. Broom it may be accepted as an established fact that the teeth and palate in several respects are more human than those of any of the living anthropoid apes. The geological and faunal evidence alike debar them as too recent to stand in the direct line of human descent, but on the view that they derive from a dryopithecid ancestry of Miocene date, they support the conclusion that the dryopithecid stock was endowed with a potentiality of evolutionary development in the direction of the Hominidæ so far as teeth and palate are concerned.

Turning to the ape-like men, the recently discovered examples of Pithecanthropus, and especially the early infantile skull from Modjokerto, with which are here included the fossils from Choukoutien referred to the genus Sinanthropus, have served to confirm the Hominid status of the Pithecanthropus group. Despite many primitive features of the skull, brain and dentition, the limb bones are closely comparable with those of modern man. If the modern characters of the human limbs had already been acquired so early as the beginning of Pleistocene times, the point of divergence of the Hominidæ from the Simiidæ must have been correspondingly more remote.

The evolutionary origin of the Pithecanthropus group is entirely conjectural. Presumably it is derived from a dryopithecine ancestry; but here there is a conspicuous gap in the palæontological record.

In the classical examples of Neanderthal man, the skeleton shows the development of a number of somewhat specialized characters from which it is inferred that the type could scarcely have given rise to *Homo sapiens*. As no transition types of later date have been found, it is legitimate to assume that Neanderthal man became extinct. It is significant that typical Neanderthal forms belong to the later phase of the period, whereas the remains belonging to the earlier part of the Mousterian epoch, such as, for example, those found at Krapina in Croatia, are less typically Neanderthaloid. This agrees with the occurrence of pre-Mousterian types (for example, Ehringsdorf, Steinheim, Swanscombe) which show a close resemblance to *Homo sapiens*. There can be little doubt that they were the precursors of modern man.

The Pithecanthropus group then almost certainly provided the basis for the development of later types of man. Of these, one is represented by the rather specialized Neanderthal type of later Mousterian date—an aberrant line—and a second by types of early Mousterian and pre-Mousterian date which were less distinctively Neanderthaloid and more akin in their anatomical features to *Homo sapiens*.

DEVELOPMENTS IN ELECTRIC SURGE RECORDING

IN 1933 a considerable amount of investigation had already taken place, chiefly outside Great Britain, with the view of determining, by means of special devices called klydonographs, the effects of lightning discharges upon overhead lines. The klydonograph is an instrument in which an electric discharge takes place on to a photographic plate or film, the resulting impression affording a record of the characteristics of the discharge. The advent of the National Grid in Great Britain stimulated interest in the subject. Whilst it was seen that the published information from various countries could be usefully applied, it was also realized that, as the results were dependent on so many variables, this needed great care, and that a similar and independent investigation could with advantage be carried out in Britain.

This was undertaken by the British Electrical and Allied Industries Research Association, with the co-operation of the Central Electricity Board and the Yorkshire Electric Power Company. The complete investigation included the use of a high-voltage cathode ray oscillograph and magnetic links in addition in continuously recording klydonographs, but only the last mentioned are to be considered here. It was agreed that these instruments could not be regarded as accurate peak surge voltmeters, but that they were capable of indicating the approximate magnitudes, polarities and times of occurrence of voltage surges.

The investigation was begun in 1933, on an 11 kv. line owned by the Yorkshire Electric Power Co. Three klydonographs were coupled to the line by means of concentric-cylinder type capacitance 'potential-dividers'. It was soon found out that the klydonographs were not suitable for unattended use, and new ones containing many improvements were developed. Progressive elimination of defects resulted in trustworthy and satisfactory operation by May 1937, since when no noteworthy trouble has been experienced.

On April 5 J. L. Candler read a paper before the Institution of Electrical Engineers on developments in surge recording by means of the klydonograph. This paper is based on the E.R.A. report Ref. S/T 26, and is mainly concerned with the instruments and their auxiliaries. The principle of operation of the klydonograph is fairly simple. A high-voltage electrode is placed in front of and touching a photographic film. The momentary application of a high voltage across the electrode will produce a distinctive figure on the film after development. This figure is known as a photographic Lichtenburg figure or klydonogram, and from its size and type certain features of the voltage causing it can be deduced. By causing the film to slide between the electrodes at a known rate, the time of occurrence of the surge can be estimated. Generally two films and two pairs of electrodes are used. By comparing the two concurrent figures the polarity of the voltage producing them is definitely determined.

The complete instrument consists essentially of three parts: (1) a light-proof box containing the spools of unused films, the electrode system and the feed-control sprocket wheels; (2) a smaller light-proof box, containing spools on to which the used film is wound; and (3) a compartment containing two clock-work motors. Hundred foot reels of 35 mm. film are used and the travel rate is 1 inch an hour. Thus the films last for about seven weeks, but provision is made for cutting off the used film when desired, and two interchangeable take-up boxes are provided for each instrument.

In the latest type many improvements have been introduced and little trouble is now experienced. It is essential that in making tests on klydonographs the conditions should stimulate practical conditions as nearly as possible. For this reason a test hut was erected in the field behind the laboratory building. The requisite voltage is applied by a transformer either directly or through the potential divider. Experience since 1937 indicates that mechanically the devices have attained a very high standard of perfection, and that electrically the performance cannot be improved further with this type of instrument.

No surges considered to be due to lightning were recorded on the Rayleigh-Southend line, on the lines in South Scotland or at the (G.E.B.) Creekmouth transforming station. Recording on the Rotherham–Doncaster line and the Thornhill–Barugh line each yielded fifteen. Surges due to switching were numerous, but they are usually uni-directional and are approximately equally divided between the two polarities and limited to not more than twice the normal voltage.

MECHANISM OF PHOTOSYNTHESIS

IN a recent article (*New Phytol.*, 39, 33; 1940) K. Wohl has presented a notable addition to the literature on the kinetics of photosynthesis in green plants, in which a model is put forward based largely on the results of Emerson, Warburg, and their collaborators. Assuming that the light-sensitive reaction requires 4 quanta/mol. carbon dioxide, as first demonstrated by Warburg and Negelein, the author suggests the following type of reaction:

$$\underbrace{X_0 \xrightarrow{h\nu} X_1 \xrightarrow{h\nu} X_2 \xrightarrow{h\nu} X_3 \xrightarrow{h\nu} X_4 \xrightarrow{-O_2-CH_2O} X_0}_{\uparrow \qquad\qquad\qquad +H_2O + CO_2} \quad . \quad (1)$$

Recent work on quantum efficiency is later reviewed in the paper. The high value of this efficiency and the shape of the rate/light-intensity curve indicate that none of the intermediate photoproducts is lost and that X_4 is also produced in an irreversible way. The carbon dioxide is therefore considered attached to a 'reducing centre' which is coupled, in an energetic respect, to a number of chlorophyll molecules. Absorbed quanta may then pass to the reducing centre which, together with its associated chlorophyll, may be referred to as a *functional* photosynthetic unit. Considerations are put forward which support the existence of such a unit, and a comparison is made with the *numerical* unit of Emerson and Arnold. Figures are presented both for the *functional* and the *numerical* units in a number of plants, calculated from experiments in continuous and in flashing light, and both kinetic and optical models are set up.

As regards the sequence of events figured in (1), experiments in flashing light indicate that the four light processes occur successively with no prolonged dark reaction between. The Blackman reaction $X_4 \rightarrow X_0$, unlike most physiological reactions, deviates widely from the simple Arrhenius reaction. One explanation is that the Blackman reaction occurs in a number of steps of reaction time τ_1, τ_2, τ_3. . . . Taking two reactions only, for simplicity, τ_1 is shown to belong to a reaction of high activation energy and is several orders of magnitude smaller than τ_2 which is coupled to a low activation energy. The two reactions are therefore of entirely different types. From the calculated values of $\tau_1^{(0)}$ and $\tau_2^{(0)}$ (hypothetical reaction times at infinitely high temperatures) the author shows that τ_1 relates to a monomolecular reaction and τ_2 to a bimolecular. The calculated value $1/\tau_1^{(0)}$ surpasses the theoretical figure even for a monomolecular reaction. This is accounted for by the introduction of an entropy factor $T\Delta S$, replacing the activation energy A_1 by the free energy $A_1 - T\Delta S$ in Arrhenius's equation. This gives a figure of the correct order of magnitude only if a considerable number of atomic bonds are broken during the reaction period τ_1.

It is suggested that at least six such breakages occur and that the six CH_2O groups produced combine immediately to, for example, a hexose. These six groups must be produced successively at the same reducing centre, and photosynthesis would then be a 24-quanta process. The bimolecular reaction is taken to be the formation of an oxygen molecule. Ninety-three references are given.

RAIN FOREST OF SOUTHERN NIGERIA

DR. P. W. RICHARDS, of the Botany School, Cambridge, in a recent paper, states that it forms the first part of the results of the Cambridge Botanical Expedition to Nigeria and it aims at being a description of a typical region of the West African Rain Forest—a chief object being to compare the rain forest of this area with those previously studied in British Guiana and Sarawak ("Ecological Studies on the Rain Forest of Southern Nigeria". (1) "The Structure and Floristic Composition of the Primary Forest", *J. Ecology*, 27, 1; Feb. 1939. Univ. Press, Cambridge). The reasons for making such a comparison are not stated. The author states on more than one occasion that "the Rain Forest of the whole of South-Western Nigeria is situated near its climatic limits".

Discussing the remarkable uniformity of the forest attributed by Mildbraed to the great climatic changes the region has suffered in the past, causing great migrations of floras and levelling local peculiarities, the author says: "if this is so, it is easy to understand why regions on the extreme edge of the Rain Forest Area, such as South-Western Nigeria, should show a marked poverty in species". This insistence by the author is curious. Perhaps it is based on his statement that "it is generally admitted that the Cameroons is one of the richest regions of the African Rain Forest and is probably to be regarded as the chief centre of evolution of the Rain Forest flora". Yet the rain forest belt stretches to the west of Nigeria through the Gold Coast and through the French Ivory Coast, where it occupies extensive areas; which, in some parts, are claimed to be as fine examples and to produce as large a percentage of high-quality timber—mahoganies and so forth—as any other portion of the belt on the Coast.

The main differences in the author's comparison of the south-western Nigerian forest with that of British Guiana and Sarawak are: (1) that the first and second tree stories in Nigeria are more open, whilst the largest proportion of the third story is true third-story species; (2) the relative floristic poverty of the Nigerian forest; this poverty applying to all three stories of trees, to the shrub and herb layers, and to the climbers and epiphytes. In respect of single species dominance, the author considers the Nigerian rain forest as intermediate between British Guiana and Sarawak. Dr. Richards is of opinion that (1) and (2) above may be due to unfavourable climatic conditions, though with reference to (1) he quite correctly adds "though it is impossible to exclude human interference as a possible cause".

SEVENTY YEARS AGO

NATURE, vol. 2, June 23, 1870

The Unit of Length

"The battle of the Standards is over, and we may say the Metre has gained the victory. The need of a new system of weights and measures to amend the strange diversities which disfigure our practice being admitted, the question has once more been started—Should we once for all found our system on a natural basis ?" The seconds pendulum had been suggested but dismissed on account of the difficulty of ascertaining the real length of a normal pendulum. The advocates of the metre admit that greater accuracy is obtainable than that achieved by the French philosophers at the end of the eighteenth century, but point out that it is already a cosmopolitan unit, widely recognized, and in general use among many nations. Any slight error in its determination is more than counterbalanced by the extreme simplicity, symmetry and convenience of the metric system.

A Royal Commission which has considered the introduction of the metric system in Great Britain has recommended its legalization. "Since the complete substitution of the metric for the present practice is now practically certain, would it not be much better to prepare for the change and carry it into effect as speedily as possible ?"

Advertising

"WE have just seen a bill-head or order to which we think it necessary to call attention. On a scroll at the top is a name which, together with the address, which is on another scroll, we suppress. . . . In the centre is a coat of arms and crest surrounded by a garter, on which is printed *Fellow of the Chemical Society, London.* We have no wish to infer that this gentleman is not a most eminent chemist, but we do most emphatically protest against the membership of a learned society being turned to account for advertising purposes."

Museums of Natural History

"THERE is no doubt of the popularity of museums of natural history with the lower classes. That it is otherwise with more educated people is perhaps attributable to the fact that hardly any scientific knowledge is to be gained by a cursory inspection of crowded collections arranged with reference to economy of space rather than to the existing conditions of zoological science. It must not be forgotten that the sentiment of mere wonder . . . was satisfied, or at least blunted, in early childhood, in the case of those of us who have had access to well-illustrated books, and to the zoological gardens of great cities."

THE indifference of agriculturists to scientific research has been illustrated by the refusal of the Council of the Royal Agricultural Society to publish an account of the investigations which have established the truth of the old bucolic dogma, that berberries produce rust on wheat growing in their vicinity. There is now no doubt that the berberry-rust and the wheat-rust are two different stages in the genetic cycle of *Puccinia graminis*.

FORTHCOMING EVENTS

Monday, June 24

ROYAL GEOGRAPHICAL SOCIETY, at 3 p.m.—Annual General Meeting.

Tuesday, June 25

ROYAL ANTHROPOLOGICAL INSTITUTE, at 5 p.m.—Annual General Meeting.

Prof. A. R. Radcliffe Brown : "On Social Structure" (Presidential Address).

AUSTRIAN ACADEMY IN GREAT BRITAIN, at 5 p.m.—Prof. Dr. Max Neuburger : "The Contribution of the Vienna Medical School to Medical Science".

Friday, June 28

ASSOCIATION OF SPECIAL LIBRARIES AND INFORMATION BUREAUX (in the Lecture Hall of the Science Museum, South Kensington), at 5 p.m.—Miss E. W. Parker : "The ASLIB Register of Technical House Journals".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned :

HEAD OF THE ENGINEERING DEPARTMENT of the Burnley Municipal College—The Director of Education, Education Offices, Burnley (June 26).

DIRECTOR OF EDUCATION for the Borough of Hyde—The Director of Education, Education Office, Union Street, Hyde (June 27).

LECTURER IN CHEMISTRY at the Rutherford Technical College, Newcastle-upon-Tyne—The Director of Education, City Education Office, Northumberland Road, Newcastle-upon-Tyne 2 (June 29).

EDUCATION OFFICER to the Community Service Council for Durham County, Ltd.—The Director, Hallgarth House, Durham (June 29).

ASSISTANT LECTURER IN PHYSICS—The Registrar, The University, Manchester 13 (June 30).

CHEMIST AND BACTERIOLOGIST to the Borough of Chelmsford Water Undertaking—The Town Clerk, Municipal Offices, Rainsford House, Chelmsford (endorsed 'Chemist and Bacteriologist') (July 1).

LECTURERS IN AGRICULTURE (two required)—Sudan Government London Office, Wellington House, Buckingham Gate, London, S.W.1 (quoting "Lecturer in Agriculture") (July 8).

COMMISSIONED ORDNANCE MECHANICAL ENGINEERS in the Indian Army Ordnance Corps—The Secretary, Military Department, India Office, London, S.W.1 (quoting "Ordnance Recruitment") (July 8).

TWO TEACHERS (men) OF ENGINEERING SUBJECTS—The Principal, South Dorset Technical College, Newstead Road, Weymouth (July 27).

ASSISTANT LECTURER FOR MINING—The Principal, County Secondary School and Cumberland Technical College, Workington.

THE RANKS OF LIBERTY

THE ranks of liberty have suddenly been thinned ; physically they are weaker, but the blow has made them spiritually stronger. The action of the present French Government at Bordeaux has without doubt resulted in the capitulation of the mother country of the French Empire ; what line of action will be followed by her Empire over-seas remains to be seen.

No one can lay a finger on a specific reason for this catastrophe ; though the causes leading up to it have been manifold. It would be useless to close our eyes to the fact that one of the major causes has been—science. As the Prime Minister pointed out in the House of Commons on June 18, if we fail, the world will sink into the abyss of a new Dark Age, "made more sinister and perhaps more prolonged by the lights of a perverted science".

When the history of the present time, and especially of the period leading up to it, comes to be written, blame will be, rightly or wrongly, apportioned. Men of science have often heard their calling castigated for the use to which it is put in making mass murder, torture, bad faith and even treachery so easy as it is to-day. So, when the time comes, men of science will receive their portion, probably in excess, of the blame usually meted out by superficial thinkers. As we pointed out in NATURE of June 15, p. 910 : "the conscience of science is clear. She offers man a rope to skip : she cannot be blamed if he chooses to hang himself with it." Thus are we glad to note that the Prime Minister realizes that it is a "perverted" science which is being utilized to further Totalitarian aims. We claimed that "science is willing, nay eager, to assist [man] along the path of prosperity and happiness which she has helped to provide." Alas, many of those in authority are still unable or reluctant to grasp the great importance of what science and scientific workers offer to the advancement of civilization.

Much has been said and written about the social relations and implications of science. Men of science were becoming more and more aware of the humanistic aspect of their work, and great efforts were being made to bring the blessings of science to the forefront. But little has been done to prevent the perversion of science. An all too clear object lesson is now before us ; and when the question of reconstruction can be usefully considered, this aspect must receive its due measure of attention—and a very large one it must be.

Meanwhile there is much to be done at once. Our thoughts turn to our French colleagues in their present sufferings. At the moment their fate is not known. Many of them are undoubtedly remaining at their posts. What the future holds for them remains to be seen ; if they are treated as the men of science of other occupied territories are being treated, they will be able to carry on their work in a modified form, regimented as regards hours, etc.—not an ideal atmosphere for scientific work.

It is quite possible that some French scientific workers have reached Great Britain, and others may perchance follow. These are early days, and one cannot foretell how many or what type of scientific worker may succeed in obtaining sanctuary in Great Britain. But whoever comes must be given not only sanctuary, but also an opportunity to pursue his calling. Those whose work is of immediate importance to the war effort should be absorbed into the various Government research departments ; the others, surely, will not look in vain to our universities and other institutes of scientific research.

Over a period of several years, these centres of research have responded admirably to the call for aid from refugees from divers countries. Many such aliens have now been inevitably interned. Our French colleagues constitute a different category. Everything must be done to help them, though we fear that the terms imposed upon France will preclude most French men of science from leaving their country and continuing their work in that atmosphere of freedom which still prevails in Great Britain, and for which all British and all free French will continue to work and fight.

SCIENCE AND THE WAR EFFORT

SOON after the present Government took office, the Minister of Supply, Mr. Herbert Morrison, made a powerful appeal for intensification of effort in the production of munitions and other commodities, in the course of which he used a phrase, "Go to it", that has already become a slogan. He asked for speeding up of manufacturing processes, the over-riding of trade customs and the hard-won privileges of the trade unions, and in general the subordination of everyone and everything to the supreme task of winning the War. The military disaster in France has accentuated our need. From now on, Great Britain is the immediate target, and the need for munitions to replace losses in France, as well as to provide for the needs of the future, should require no emphasis.

The immediate demands of our war effort upon scientific workers and other technical experts are, of course, for the provision of the skilled work of control, in the testing of materials and products, and in the supervision of processes to ensure that the production of munitions of war, whether of explosives, guns, tanks, aeroplanes, war-chemicals or other products is smoothly, efficiently and safely maintained. This demands the continuous scrutiny of existing products and processes with the view of improving them and of replacing them by others superior to those used by the enemy.

All this, however, is only the first and possibly the least significant part of the contribution of science, great as are the demands it makes on the scientific worker for untiring accuracy, patience and skill. The nation's production of armaments must in some measure be related to the natural resources available. Unless the fullest possible use is made of these, we may be wasting our reserves of man power, of transport, or of foreign exchange.

It is difficult indeed to visualize the many ramifications here involved. The most effective utilization of coal, for example, affects not merely the manner of burning raw coal, its carbonization or conversion to coke or gas, or the generation of electric power. The by-product position has to be considered with reference to raw materials which it provides for explosives or other branches of chemical industry. Questions of atmospheric pollution and the like are also linked up with this question of efficient utilization of fuel, and it needs little imagination to visualize the reactions upon public health, problems of transport and the location of industry.

The importance of the scientific contribution is equally important in regard to questions of crop production. The decision as to which crops attention should be concentrated upon involves not merely an accurate knowledge of soil and climatic conditions, questions of shipping space, the interlocking of export policy and exchange reserves. It is linked up also with the whole policy of agriculture and food supply.

The importance of this latter question has been repeatedly stressed of late by Sir John Orr, Sir Daniel Hall, Mr. C. S. Orwin and others, who in the daily Press and elsewhere have stressed the necessity for a scientific policy of food production and directed attention anew to the valuable services rendered during the War of 1914–18 by the Food (War) Committee of the Royal Society. Their arguments have since been strongly endorsed in the Fourth Report of the Select Committee on National Expenditure, which expresses serious doubts as to whether sufficient use is being made of scientific research in regard to the wider issues in planning of food policy, such as the allocation of sugar or the planning on the basis of the fullest scientific study of a ration adequate in calories, etc., at a less cost in shipping and external currency than with the present normal form of diet. At present there is evidence that allocations of supplies are being made on the basis of a rough and ready compromise between various interests, and not on the basis of a plan scientifically devised in the interest of the country as a whole.

The problems of scientific discovery and progressive industry must be of paramount importance in our war effort. Ultimately such problems, of course, resolve themselves into the effective utilization of natural resources—the adaptation of industrial processes and methods to provide the products required by a war-time economy, whether to meet the demands of the Fighting Services, essential civil needs or the requirements of the export market, from the raw materials available under war-time conditions. Equally urgent is the question of developing or expanding processes for products which previously have been imported in whole or in part from countries which are now cut off. Such development or expansion may involve in the first instance intensive scientific research; for example, in the field of medicinals it may be necessary to elaborate processes for products which are urgently required to meet immediate war needs. Other scientific work may be required for the production of scientific apparatus on a much larger scale, or for the supply of products such as dyestuffs to seize the opportunities in export trade which have been opened to us by the blockade.

In the main, such problems are already being tackled by industry. There must, however, be continuous improvement both of our products and processes in the light of new knowledge, whether for offensive or defensive purposes, the service of essential civil needs or the export market, to establish an overwhelming superiority over those used by the enemy. This is a matter which involves the most effective utilization of our whole structure for fundamental as well as industrial research, and the bringing into the service of our needs that creative intelligence which is one of our greatest assets, as it is one of the great values in the heritage which we are defending. Here, above all, scientific workers must make their main contribution, not merely in the skill and resource with which they grapple with the immediate problems confronting them, but also in visualizing new problems and in organizing the most effective mobilization of all the resources of scientific knowledge or personnel to serve our myriad needs in this desperate struggle.

Nor is this merely a matter for the application of scientific knowledge and methods on the production side of industry alone. Science has almost equally important contributions to make in perfecting our methods of civil defence, in the mitigation of strain imposed by such conditions as the black-out or evacuation measures, and in safeguarding the health of the industrial workers and indeed of the whole civil population.

If we are to secure the maximum output from our mechanical equipment, very careful attention must be given to such questions as hours of work, canteens, rest periods, and the organization of holidays, so as to avoid interruption of output or throwing a strain on transport. The report already issued by the Industrial Health Research Board on industrial health in war has emphasized the dangers to efficiency as well as to health which may result from excessive hours or continuous work without intervals for rest, and from failure to give adequate attention to such matters as lighting, ventilation or accident prevention, as indicated in the experience gained in this field in the War of 1914–18. A letter from the Association of Scientific Workers on p. 1024 of this issue refers to this question, and recent utterances of the Minister of Labour and the appointment of a Factory and Welfare Advisory Board shows that the difficulties are appreciated.

Other problems, too, call urgently for scientific management. Such methods offer the best way of securing the more rational distribution of orders, increasing the mobility of labour and operating an efficient system of priority. Equally they play an important part in training the new workers required by industry for war purposes and in discovering, for example, just what kinds of skill can be acquired by intensive methods of only a few weeks duration. Technical education demands attention, for the training of highly skilled and responsible men in industry is a long-period problem, which must not be overlooked although the main and immediate problem of training is concerned with the hundreds of thousands of machine operators who are already needed.

If the tremendous drive in our industrial war effort to which we have been summoned by the Minister of Supply is to reach its full effect, it must be based on scientific knowledge and guided by scientific methods at all stages, in the planning of policy, in the development and in the control of processes and products. The contribution of scientific workers will demand the utmost vigour of creative thought and fundamental research, no less than the intense prosecution of the team-work characteristic of industrial research.

SALVAGE AND UTILIZATION OF WASTE

IT is of the very essence of war that every resource must be used to resist the advance of the aggressor. There is no room for half-measures; the War is the concern of every one of us; a steadfast purpose, high resolves and a capacity to put those resolves into action should dwell in the hearts and minds of all.

"What can I do to further the ends for which our country is struggling, to keep alight the lamps of freedom of thought and speech ?" is the question on the lips of millions of our fellows. "The work of the armed forces is clear before them; the farmer is providing essential food; the munition-workers' contribution is of primary importance. But what can I give to the cause, save by paying taxes, and by carrying on with my own work ?"

Much; and in many directions. An essential and vitally important help which every one of us may give, is summed up in the one word *economy.* Economy will indeed be forced upon us, for when the British national income at the outbreak of war was reckoned at £6,000 million per annum, the Government was taking from this income about £1,200 million. Thus £4,800 million were left in the pockets of the people. But if, owing to increased War-time effort, the national income should rise to £7,000 million, and the annual national expenditure to £4,000 million, then expenditure by the public *must* fall to £3,000 million. There is no gainsaying this. Economize we must, and it is well to begin early.

This, however, is but the passive side of war economy. Waste has a wide meaning, and while it is incumbent on each one of us to practise economy and to avoid waste, we must recognize the fact that there is an active side to the problem and another meaning to the term *waste.* Waste products of one trade are valuable raw materials for another; waste household products which in peace-time were rightly consigned to the flames, the rubbish heap, or the attic, become, in these days of war, essential parts of the national economy. Their usefulness must not be judged by ordinary economic standards; the national need is the determining factor. So important and pressing is this matter, that a special department of the Ministry of Supply—the Salvage Department—has been set up, which makes the gathering and utilization of such products its special concern.

The figures which deal with the amount of preventable waste are impressive. Thus, before the War, twenty thousand tons of paper and cardboard were thrown weekly into Great Britain's dustbins—well over a million tons a year. Such waste in war-time is almost criminal, and the Salvage Department is to be congratulated on the successful steps which it is taking to diminish this waste. During November last, the tonnage of waste paper collected was 4,500; during April of this year, 9,000.

There are few things considered less useful than woollen rags. Nevertheless, such rags are used in the manufacture of high-grade paper, and are the raw material of an industry that has flourished in the West Riding of Yorkshire for more than a century. This industry depended in the past on large supplies imported from abroad, and here, as in the paper industry, a substantial increase in the home supply will proportionately reduce the strain on shipping. They who produce, from the recesses of their wardrobes, old and long-discarded clothes, and see that they reach the appropriate distributing agency, will be doing a very real and important service. So also with ferrous (and non-ferrous) metals, all of which take on a new value as potential sources of high-grade steel.

The utilization of animal and vegetable refuse presents most curious and varied technical problems. Some of these problems have been efficiently solved; many others await solution. Most unexpected uses are to be found for various types of such refuse. Banana stalks, for example, of which many tons are available, are a most useful source of fertilizing material, and the household cooked bone has, from this point of view, scarcely any waste. One-eighth of its weight content is fat, one-eighth glue, and the remaining three quarters, properly treated, will appear as feeding meal for cattle, or as bone-fertilizer.

Here, then, is an example of work in which every one of us, townsman or countryman, child or adult, can take part. Such help as a single individual can give may seem a small matter, but in the aggregate the results obtained may be of far-reaching importance. The Salvage Department is doing its work well. In five months the number of town and other councils making returns has risen from 320 to 900, the populations which these councils represent being, in the first instance, 23 millions; in the second, 38 millions. This is a remarkable increase; but it must not be taken to imply that all the councils and local authorities in Great Britain are working at full pressure, or that they have completely developed their methods of attack on the task of the utilization of waste. Different councils have to face different aspects of the problem, and their solution calls for active co-operation between chemist, physicist, biologist and engineer. But the problem of bringing together the waste material is one to which everyone can lend a hand, and the schools can play a specially important part in this task.

Hitherto, the salvaging of waste material has been voluntary, in that local authorities have been asked to provide for the separate collection of material which can be utilized. The Minister of Supply has now announced that all local authorities with populations of more than 10,000 will be required to arrange efficient systems for the collection of salvage, and householders in these areas will be obliged to co-operate. Waste paper and cardboard, scrap metals and household bones are urgent needs, and other materials such as waste food and rags may be added to the list at a later date. The fact that a measure of compulsion is to be introduced need not deter the individual from continuing his own effort, on which, in the long run, will depend the outcome of the official drive for the collection of utilizable waste material.

A PIONEER IN PSYCHOLOGY

Psychological Issues
Selected Papers of Prof. Robert S. Woodworth. With a Bibliography of his Writings. Pp. x+421. (New York: Columbia University Press; London: Oxford University Press, 1939.) 22*s*. net.

WILLIAM JAMES once declared that psychology was not a science, but only the hope of a science. Much water has flowed under the bridges since that statement was made, and psychology may fairly be said to have proved its claim to recognition, notwithstanding that it is still split up into warring schools or sects. Few men have done so much to bring about the change as R. S. Woodworth, professor of psychology at Columbia University. As a student under James at Harvard, and later on as an assistant to Cattell at Columbia, he came under two powerful influences, which helped to shape his career, and partly explain the breadth of his interest in psychological problems, both on the physiological and on the statistical side. He has recently passed his seventieth birthday, and his colleagues in the department of psychology at Columbia, where he has taught for thirty-six years, have, without his knowledge or consent, prepared this commemorative volume. It was a gracious act, and one which will be warmly approved by many who only know Prof. Woodworth by his writings.

Most students of psychology know him by his "Psychology", a standard work now in its third edition, and by his "Contemporary Schools of Psychology" (1931), a book which bears the clear impress, not only of its author's ripe learning, but also of his wisdom and his sanity of judgment. Most of Prof. Woodworth's original work, however, consists of contributions to scientific journals spread over a period of more than forty years, with a list of titles covering a dozen octavo pages. This volume comprises some of his most distinctive work, ranging from an early note on the alleged rapidity of dreams (1897) to a paper for the *American Journal of Psychology* in 1937.

Not the least interesting part of the book is the chapter of autobiography written in 1932 for a comprehensive volume recording the careers of distinguished living psychologists. To an English reader there is one rather odd statement in this chapter. Prof. Woodworth relates that when he began studying psychology in September 1890, James's "Principles" had not yet appeared, and that there was probably no book in existence, at any rate in English, which could be recognized to-day as a text-book in psychology, the nearest approach being Carpenter's "Mental Physiology", a book dating from about 1870. This is surely rather hard on Prof. James Sully, a true man of science, whose "Outlines of Psychology", published in 1884, had completely superseded such books as Carpenter's and Bain's by the time that young Woodworth set out upon what proved to be a career of distinction. Perhaps it has made no difference in the end (who can tell?); but it must have made a difference at the beginning, that his advisers were not up to date.

CRYSTALLINE ENZYMES

Crystalline Enzymes
The Chemistry of Pepsin, Trypsin and Bacteriophage. (Columbia Biological Series, No. 12.) By John H. Northrop. Pp. xv + 176. (New York: Columbia University Press; London: Oxford University Press, 1939.) 15*s*. net.

THE chemical nature of enzymes has in the past been the subject of acute controversy. It has seemed impossible to many investigators to associate with molecules of high molecular weight their extraordinary power of controlling the complex reaction of living systems. Yet it is becoming more and more difficult to separate the study of enzyme activity from that of the proteins with which it is associated, and this is particularly true when we deal with crystalline enzymes. The characteristic activity of enzymes provides the most delicate test for their presence; they may be detected in solutions much too dilute to give positive protein reactions. But the enzyme crystals so far obtained are all protein crystals, and their preparation has proved an important step in relating the chemistry of enzymes to that of proteins as a whole. Since Sumner's first isolation of crystalline urease in 1926, some twelve different enzymes have been obtained in crystalline forms the variety of which reflects their diverse and specific chemical character. Of these, one of the most remarkable groups is that of the proteolytic enzymes studied by Northrop and his collaborators.

Northrop's present monograph is essentially an authoritative account of his own researches and does not deal, except in a general introductory way, with crystalline enzymes as such. It does include a general account of the problem of enzyme catalysis and reaction kinetics, but the sub-title of the book provides a more accurate description of its scope. For the principal beauty of Northrop's work lies not so much in the investigation of a large number of different enzymes as in the isolation of several closely related proteins and the study of their reactions one with another. We have here the beginnings of a chemistry of pepsin and trypsin in the same sense that we might speak of the chemistry of aniline—including the preparation of crystalline derivatives and the conversion of one protein into another and related and crystalline protein. But this chemistry of molecules of weight 30,000–40,000 is on a different scale of magnitude altogether from that we are accustomed to meet in classical organic chemistry.

Pepsin itself crystallizes in very characteristic hexagonal bipyramids which may, like many other protein crystals, contain a large proportion of impurities. The separation of different protein constituents during purification is best followed by solubility measurements, which distinguish pepsins derived from different sources, for example, swine and chicken pepsin, when other tests fail. So far it has proved impossible to relate the activity of pepsin to a particular prosthetic group, though it is evidently dependent on the presence of tyrosine in the molecule. One of the several reactions supporting this is acetylation, which leads under different conditions to the production of three different acetyl pepsins, all of them practically identical in crystalline form with pepsin itself. Only as the tyrosine groups are attacked in the second and third of these does the activity fall, first to 60 per cent, then to 10–15 per cent of its original value. A more profound modification of the molecule is involved in the formation of pepsin from its inactive precursor pepsinogen, which can be obtained crystalline in fine needles. Unlike pepsin, pepsinogen is stable in alkaline solution and is converted into pepsin by an autocatalytic reaction in acid solution. This reaction probably involves some splitting of the protein molecule; the two proteins are actually very similar in composition apart from the rather higher amino nitrogen content of pepsinogen.

A second important group of enzymes are the proteolytic enzymes of pancreatic juice, trypsin, chymotrypsin and carboxy peptidase. Trypsin and chymotrypsin both form particularly complicated series. Both have precursors, chymotrypsinogen (long needles) and trypsinogen (small triangular plates), which are converted into the active compounds under the influence of enterokinase, trypsin, and in the case of trypsinogen, a mould kinase. Chymotrypsin itself crystallizes in rhombohedra, but from its solutions separate two other enzymes, β-chymotrypsin (plates) and γ-chymotrypsin (short prisms). These are probably produced by slight hydrolysis of chymotrypsin itself, as they have lower molecular weights. Although similar in activity, they are distinct proteins with different solubilities which form solid solutions below *p*H 5·0 but crystallize independently between *p*H 5·0 and *p*H 6·0. The formation of trypsin from trypsinogen is complicated by the presence of a most interesting compound, trypsin inhibitor, which appears to be a polypeptide of molecular weight about 6,000. This crystallizes in long hexagonal prisms and with trypsin forms a 1 : 1 compound, also crystalline, inhibitor trypsin compound.

Among the most remarkable reactions described is that of reversible "denaturation", which is shown particularly by pepsinogen, chymotrypsin and trypsin. Solutions of these proteins may be heated to boiling and cooled again without loss of activity or potential activity. If the hot solutions are tested it is found that the protein present is inactive and can be precipitated by the addition of salt as if it were denatured. In the case of pepsinogen the protein is completely native below 50°, completely changed above 70°, and yet activity is restored on cooling. It would perhaps be better to use some special term instead of denaturation for this change, such as degeneration, as Astbury has suggested, since on long heating further changes take place which prove to be irreversible.

The study of the bacteriophage is still a stage outside the scope of the title of the book. It behaves in many ways as a nucleoprotein and its activity is destroyed by chymotrypsin, though not by pepsin or trypsin. Also heat-inactivated phage may be reactivated under certain conditions. But no phage has yet been crystallized, and Northrop concludes that it is impossible on the data obtained up to the present to decide whether phage should be classified with enzymes or with cells.

Northrop's monograph is throughout largely an account of work in progress and indeed of work which it is to be hoped will progress a great deal further. It is chiefly designed for the research worker in the field, who should find the detailed tables of preparations included in the appendixes invaluable. But the subject itself is of such interest and its presentation so clear that the book should have a very much wider appeal.

In conclusion, it would be worth buying if only for the very beautiful photographs of enzyme crystals that it contains.

Dorothy Crowfoot.

VIBRATION IN ENGINEERING PRACTICE

Mechanics Applied to Vibrations and Balancing

By D. Laugharne Thornton. Pp. xii+529. (London: Chapman and Hall, Ltd., 1939.) 36*s.* net.

Although there is no dearth of recent books on the subject of vibrations and the methods of balancing them, they all assume on the part of the reader a considerable knowledge of, and familiarity with, the dynamical principles on which the whole reasoning and mathematical treatment are built up. This, of course, is an essential preliminary but, owing to the different modes of presentation adopted by individual authors, there is for the average reader a somewhat difficult transition to be effected in switching from one form to another. For the designer, too, who has not been closely engaged in the more difficult problems of balancing, the first requisite is that these fundamentals should be clearly re-stated in direct association with the development of the main argument.

In this book, the author has dealt with each phase from the simplest beginnings, and has made a clear exposition of the basic principles the starting point of each argument. Although writing primarily for engineers and dealing with his subject in terms of units appropriate to the requirements of practical design, he has at the same time been sufficiently analytical to give his work a definite value to the student of physics, for whom an unusually wide range of examples is provided. On the mathematical side, a good working knowledge of the elements of calculus and of analytical geometry is a sufficient pre-requisite, as, where additional mathematical equipment is required, suitable explanation is given.

In the arrangement of the work two objects are clearly recognizable, the first being that of demonstrating the relation between the vibrations of unbalanced machinery and the vibratory motions thereby set up in foundations and supporting structures. These vibrations and their effects are particularly exemplified in chapters dealing with the influence of aero-engines on their fuselages and those of stationary, locomotive and marine engines on their surroundings. In dealing with the unbalanced dynamical forces and couples associated with these and other types of machines. Lagrange's equations are employed, and are enunciated and explained in some detail because of their utility in this connexion and also because of their value as an introduction to the idea of generalized co-ordinates as used in the more advanced theory of vibrations. Lagrange's method has the advantage in this type of analysis of enabling the main parts of an engine to be considered successively, so that it is possible to trace the relative motion between two parts due to the effect of a change of load and the elasticity of the connecting materials.

The second aim which can be noted is the presentation of problems pertaining to the design of buildings to withstand earthquakes, of which the author has had unique experience. This subject is discussed and illustrated by solutions to problems in which prescribed buildings are considered as a whole and as a structure composed of interconnected beams, columns and trusses. Here, too, the important question of foundations is dealt with, and in the same group may be mentioned the vibratory effects of traffic on roads.

The range of examples introduced is much too wide to be particularly classified, but it may be mentioned that they are representative of civil, mechanical, aeronautical, structural and marine engineering, and afford trustworthy guidance for most cases met with in practice.

ROCK-PAINTINGS IN SOUTH AFRICA

More Rock-Paintings in South Africa

From the Coastal Belt between Albany and Piquetberg. Mainly copied by Joyce and Mollie van der Riet. With Notes by the same and an Introduction and Explanatory Remarks by Dorothea F. Bleek. Pp. xx+28+28 plates. (London: Methuen and Co., Ltd., 1940.) 42*s.* net.

THIS volume, which has only thirteen pages of text, one map and twenty-eight plates with an explanatory page by Miss Bleek for each sheet of plates, describes a chosen number of rock paintings in the district of Grahamstown, half-way between Cape Town and Durban. They are some of the 145 examples copied by Miss van der Riet, Mrs. Ginn, Miss Sheila Fort and Miss Bright. There are also three plates of rather mediocre rock engravings, interesting because they show the extension southwards of this type of art. Some photographs of the originals are included.

On the whole, the art of the panels reproduced is not of a very high level, although the elephant shaded in reddish-brown (pl. 16–17) is very fine and so are the clothed and equipped archers (pl. 26), recalling some of the finest panels of Natal.

Among the most interesting subjects reproduced, all purely Bushman and previous to the arrival of other races, are the line of galloping springboks (pls. 15, 17, 19, 21*A*) in red, in the style I call 'spidery'; the battle between two tribes of Bushmen (pl. 5*A*) in red; the group of kneeling archers also in red drawing their bows (pl. 6*B*); the flying birds and circles of seated men painted in red (pl. 23); the little elephants grouped in a footprint of that animal (?) (pl. 27) also in red.

We must mention certain animals with their outline drawn in red and not filled in with colour, such as those in pl. 8*A* and *B*: one of these is an antelope, not an ox, with its horn (pl. 8*A*), seen full face, an example of twisted perspective rare in South African art.

There are very few big two-colour paintings of elands, and they are poor (pls. 1 and 28); the better two-colour paintings, which are rather good, are of antelopes (pl. 5*B*) and quagga (?) (pl. 10*B*). There are a few plants (?) (pls. 14*A* and 24); a rainbow (?) (pl. 7); an apron (?) (pl. 7); a skin water bottle (?) with its cords (pl. 19) near a man who seems to be climbing skywards with a rope; the spots near him suggest a rain-making rite.

A good many superpositions of the paintings are mentioned, only some of which are shown (pl. 5 *A* and *B*); brownish-red on faded red (pl. 23); three levels, yellow, red, then black (pl. 26); the black figures are obviously the latest in pls. 7, 9, 20, 25, 26; there are several paintings of baboons. A fine white and black ostrich reminds us of the celebrated ones published by Stow with the hunter disguised as an ostrich (pl. 2).

It is a pity this volume does not contain the whole block of paintings copied, even if only as small line drawings, for the chief interest in a regional investigation lies in an exhaustive study of the superpositions and styles which it exhibits. For example, stencilled feet and hands are mentioned, but there is no reproduction of them. It is said they are sometimes older and sometimes more recent than the figures; I can only say that at Riversdale, as at Wilton, where I saw them, they were far older than the figures. No late panels are given showing sheep, oxen, horses, etc.; such plates would have been valuable, making the book more complete. I have seen, for example, at Wilton, a big group of Hottentot white sheep with fat tails.

Still we thank Miss Bleek for having, so far as she could, enriched this publication, which completes her previous magnificent volume, and encourage her to pursue her fascinating study. She has pointed out in the text, with that authority which is her right, the differences in the artistic character of the various South African regions, differences which I need not enumerate.

H. BREUIL.

EARLY BOTANY AT OXFORD*

By Dr. J. Ramsbottom, O.B.E.,
British Museum (Natural History)

JOHN JACOB DILLENIUS was born at Darmstadt, Germany, in 1684. He studied at the University of Giessen, like several of his family before him. At an early age he became a member of the Academia Naturæ Curiosorum and contributed several papers to the *Miscellanea Curiosa* of that Society from the year 1715 onwards: among other matters these dealt with American species of plants which had become naturalized in Europe; Arabian coffee and his own *ersatz* preparations made by roasting peas, beans, kidney-beans and rye, the last being barely distinguishable from the real thing; the examination of mosses and other cryptogams with the view of ascertaining their sexual organs; and an experiment made with opium he had prepared from *Papaver somniferum* grown in Europe. He also wrote on leeches and butterflies.

In 1719 he published his "Catalogus plantarum sponte circa Gissam nascentium", a work which immediately established his reputation. It contains a list of plants gathered within a circuit of about a German mile and a half—approximately 980 species of flowering plants, 200 species of Musci and 160 species of Fungi; a large proportion of the Cryptogams had not previously been described. There is a critical examination of the systems of Ray, Knaut, Rivinus and Tournefort. Dillenius himself followed Ray's system throughout his career.

It was as a direct result of the catalogue that Dillenius was invited to Great Britain. William Sherard was at that time eminent in botany, so much so that Dawson Turner called him "the Sir Joseph Banks of his time". He had studied under Tournefort at Paris and later in 1704 was appointed Consul at Smyrna and there made a collection of plants and also did antiquarian exploration. At Tournefort's suggestion he undertook the continuation of Casper Bauhin's "Pinax", and on his return to England in 1716 he devoted himself to completing the work. The neglect of Cryptogams in Great Britain led him to enter into correspondence with Dillenius in 1718, and three years later, after sending for him, brought him over. Dillenius was engaged upon naming Sherard's collection of Smyrna plants and also on the "Pinax".

By that time the second edition of Ray's "Synopsis Methodica Stirpium Britannicarum", published in 1696, had become scarce, and Dillenius was employed in helping to prepare a new edition. This was published on July 17, 1724.

In 1726 Dillenius made a tour of the west of England and Wales in company with Samuel Brewer; Littleton Brown made part of the journey.

William Sherard died in August 1728 and left his books and plants and £3,000 for the maintenance of a professor of botany at Oxford. He nominated Dillenius to be the first professor for life.

Dillenius was fully satisfied with his work on the "Pinax", but James Sherard, after his brother's death, persuaded him to write an account of the plants cultivated in his garden at Eltham. "Hortus Elthamensis" appeared in 1732 in two folio volumes of 437 pages and 324 plates drawn and engraved by Dillenius. A large number of the then known species of Mesembryanthemum are figured and also some rare British plants. Sprengel described it as a most splendid work and Linnæus as "a botanical work such as the world had not seen". But Dillenius grudged the time he had spent on it. Further, he was shabbily treated by James Sherard, who complained that "he has not studied either to adorn his book or my garden; his chief care having been to improve and advance the Knowledge of Botany"—and Dillenius had to bear the cost of the production of a work James Sherard had designed "to make himself known". Many of the type specimens are preserved at Oxford. The drawings appear to have been lost.

There was difficulty over the Oxford appointment because of James Sherard's executors going to law, and Dillenius did not take up residence in Oxford until 1734, six years after William Sherard's bequest. In 1741 he published his "Historia Muscorum", a quarto volume of 576 pages and 85 plates—mosses including Bryophytes, Hepatics, Lycopods, Algæ and lichens. The original drawings of the figures on the first seventy-nine plates are in the Department of Botany; the remaining six plates were apparently drawn and etched directly on the copper. Dillenius died in April 1747 at the age of sixty-three—the great "Pinax" unfinished.

---

*From the presidential address delivered before the Linnean Society of London on May 24, which dealt with a collection of drawings recently acquired by the Department of Botany, British Museum.

Such in outline is the life of one of the foremost systematists of his time—Linnæus says of the genus Dillenia, "of all plants the most distinguished for the beauty of its flower and fruit, like Dillenius among botanists".

Although Dillenius gained a considerable reputation from his Giessen Catalogue, this was chiefly because of the prominence he gave to Cryptogams. His Musci include not only the true mosses but also the lichens and some Algæ. For the first time mosses were split up into genera and names such as Mnion, Hypnum, Polytrichum, Bryum, and Sphagnum he took from Theophrastus, Dioscorides and Pliny.

Three years before the appearance of the Catalogue, Marsigli and Lancisi had published their letters on the nature of Fungi. Dillenius adopted their ideas, and his opinion is often quoted in the discussions which went on for a century or so. "A fungus," he says, "is a sterile kind of plant, that is to say destitute of flower and seed, arising from putrefactive fermentation, wherefore they arise chiefly during a moist and rainy period and consist for the most part of a soft and spongy substance yet retaining its characteristic look which it owes to a definite and specific juice of decay from which it originated ; and so, since by this putrefactive process the texture and elements of vegetables are considerably altered and almost destroyed, Fungi do not possess a green colour or have leaves, or even texture like other plants. Another consequence is that they usually spring up in a short space of time and are of equally short duration, or become the habitat and food of grubs and beetles, with the exception of not a few arboreal species that spring from the less liquid juices of wood and therefore last longer."

In spite of this belief which, logically, means that Fungi have no separate entity, Dillenius paid considerable attention to them and describes 162 species in his Catalogue. Drawings of 114 of these are in the present collection with 52 additional drawings. They are painted on separate pieces of paper and stuck on sheets on which the details are given. These drawings serve as the types of Dillenius's species and give his interpretations of previous descriptions.

Dillenius was recommended to Sherard "as a person very curious in mushrooms and mosses, as I perceive he is," and later Sherard writes : "I have brought over with me Dr. Dillenius who has with him most (if not all) of his *Fungi* painted". These drawings must be the ones mentioned. They are not of high artistic merit.

There is also a set of wash drawings of Fungi, all mounted on the same size of paper and arranged as if for publication. They seem to be copies, but they are from no work I know and, so far, I have not been able to match a single one of them except in Dillenius's own drawings. Can it be that they are the drawings mentioned by Sherard in a letter to Richardson dated December 26, 1723 ? "Dr. Dillenius has much improv'd in his painting. He has copied for me all Mr. Dandridge's *Fungi* and as many as he has been able to procure about London". Or are these, as Dr. Druce suggested, included in the drawings of Fungi at Oxford. These latter number 264 : the printed matter in Druce's "The Dillenian Herbaria" does not appear to support the suggestion for Dandridge's name is scarcely mentioned ; some of the Fungi are said to be from Giessen.

Another set of drawings, also in wash, is entitled "Plantæ novæ aut rariores ex Ephem. Nat. Curiosorum". It will be remembered that Dillenius himself was a member of the Academia Naturæ Curiosorum. These drawings on sixty-four sheets are copied from various plates which appeared in the Ephemerides together with full notes, and from Mentzel's "Pugillus" and Alpinus and Vesling's "De Plantis Aegypti". These, I imagine, date from his Giessen days, indeed probably when he was a student.

Although Dillenius's name is not on the third edition of Ray's "Synopsis" it would have been possible to guess that he was the editor even if it were not known for certain otherwise, for the classification adopted is practically that of the Giessen catalogue. It is common knowledge, however, that his name was omitted as "there was some apprehension (me being a foreigner) of making natives uneasy, if I should publicate it in my name". He had wished to dedicate it to Sherard and R. Richardson, "two persons that have contributed the most to its perfection", but the dedication being anonymous was "to all those Lovers of Botany, who contributed the most to the edition". There was even a suggestion that Isaac Rand's name should be given as editor, which apparently Sherard approved of, though he had himself done far more work on the "Synopsis", having on occasion worked ten hours a day on it. The "Synopsis" was illustrated with twenty-four plates. The only reference I have found to the fact that Dillenius did these is in a letter from Sherard to Richardson in which he says : "I know nothing further Dr. Dillenius has to do to the *Synopsis*, but the getting grav'd a few more plates, which may be done whilst 'tis printing". Richardson sent the money to pay for two plates, but Sherard returned it saying that it was a proper charge upon the publisher. The present collection contains the original drawings of all the plates except plate 1, though a few of the figures are missing ; the drawing for plate 23 is in pencil in an unfinished state. The original figures of plate 1, which illustrate Fungi, are amongst the Oxford drawings, according to Druce. Most of the drawings have the red chalk used in engraving still showing on the reverse side. But the interesting fact is that apparently it was intended that there should be sixty-eight plates. I have not traced any reason why all were not published.

The collection also includes a number of British plants. The specimens are in the Dillenian Herbarium at Oxford. There are further fifty sheets of drawings of plants probably from Giessen, and also sixty-three drawings of rushes, sedges and grasses.

The most numerous drawings are a set of about 320 labelled "Designationes and Icones plantarum in Horto Oxoniensi crescentium . . . 1744, 1746 dipictae." They are of great artistic merit and it need not be stressed that they are botanical drawings. In my opinion they place Dillenius among the front rank of botanical artists; it scarcely seems possible that they are by the same hand as some of the earlier drawings.

The Oxford Botanic Garden dates from 1621 and had only been planted with "divers simples for the advancement of the faculty of medicine" when the Civil War broke out. Jacob Bobart the elder was the first gardener appointed, though it seems that Lord Danby, founder of the garden, had previously negotiated with John Tradescant. The definite agreement between Lord Danby and Bobart was drawn up in 1641. Under Bobart's care the garden acquired a great reputation, and a catalogue of the plants there cultivated was published in 1648; 1,600 plants are included of which 600 were British. A second edition appeared ten years later with Philip Stephens and William Brown as co-editors with Bobart. Jacob Bobart the younger succeeded his father as keeper of the Physic Garden in 1679. There are two manuscript catalogues of plants growing in the garden and its neighbourhood in the Botanical Library at Oxford, and a number of manuscript lists of seeds and plants mostly sent or received by Bobart, in the Sloane Library.

After Bobart's retirement in 1718 there was no activity until the appointment of Dillenius. Sherard and others sent plants and seeds, but the neglect which had begun as Bobart grew old and feeble continued until 1734. Linnæus's famous visit to Oxford took place in 1736. It is probable that his main object was to see Sherard's herbarium, which in his judgement excelled all others in European plants, but the opportunity of meeting Dillenius was doubtless an additional attraction. There are several accounts of this visit. Dillenius, writing to Richardson, said that the visit lasted eight days, whereas Linnæus says that the learned Dillenius was at first haughty and distant, conceiving the "Genera Plantarum" to be written against him; but that he afterwards detained him for a month, without leaving him an hour to himself the whole day long, and at last took leave of him with tears in his eyes, after giving him the choice of living with him until his death, as the salary he thought was sufficient for them both.

By collating these various lists with the present drawings it should be possible to gain some idea of the plants in cultivation at Oxford when Dillenius was professor.

What was the purpose Dillenius had in mind in preparing these drawings? They were done with such care that it scarcely seems credible that they were drawn merely for amusement. We know that Dillenius regretted every moment away from the "Pinax" and yet here we have an enormous amount of time spent with what seems to be no purpose. Was it that Dillenius had in view the preparation of a volume dealing with the Oxford garden similar to "Hortus Elthamensis"? He certainly would have found it more congenial to work as he pleased than under the selfish criticism of James Sherard.

Dr. Druce overlooked the fact that Dillenius was a correspondent of John Bartram. His letters were usually sent through Peter Collinson, who also distributed seeds collected by Bartram. In 1737 Collinson sends names of his plants from Dillenius, and Dillenius received collections of seeds and plants until 1742. Bartram also collected mosses. "Before Dr. Dillenius gave me a hint of it, I took no particular notice of Mosses, but looked upon them as a cow looks at a pair of new barn doors."

We know that Dillenius was thoroughly dissatisfied at the loss he encountered by having to finance the publication of "Hortus Elthamensis". At James Sherard's desire he printed off 500 copies, but decided to have only 145 copies of the plates. Half a hundredweight of the paper—best Dutch paper—he sent to Bartram through Collinson, who wrote that it would "make noble books for specimens" and "think will furnish thee with paper for specimens, and for seeds, for thy lifetime". Drawings of some of the plants grown from Bartram's seeds are in the collection.

The last of the Dillenian material about which I wish to speak is the manuscript "Classis of Water Plants". It consists of thirty-two pages evidently written while in England and probably before he went to Oxford. He divides the plants into two groups: (1) such as bear neither (conspicuous) flowers, nor seeds, but propagate themselves by young leaves, growing out of the sides of their mother plants; (2) Apetalous seed-bearing water plants.

The account of each genus begins with the etymology of the Latin name followed by a generic description with references to figures and literature. For each species there is a description, place, use, synonomy, and critical remarks. The strange thing is that the account of Class I (six pages) is in English, that of Class II is in Latin. Obviously the work was intended for publication but, though it seems a fair copy, was never finished.

The full account of these additional Dillenian manuscripts will supplement that given by Druce and Vines in their "The Dillenian Herbaria". At the present time, it is interesting to note that the preface to that work dated 1907 ends: "At a time when two great and partly estranged nations are being brought closer together, may this work, insignificant in itself, yet as being compiled in the twentieth century by a British student to bear witness to the eminent service rendered to Botanical science in this country by a German botanist in the eighteenth, be an augury for their more kindly feeling and cordial co-operation in the progress of science".

OXIDATION OF METALS AND THE FORMATION OF PROTECTIVE FILMS*

By Prof. N. F. Mott, F.R.S.,

University of Bristol

A CHEMICAL process in which one of the reacting substances and also the product of the reaction are solid has one feature not shown when the product is gaseous or liquid; the product must necessarily form a barrier between the reacting substances, so that the reaction can only proceed either if the product is continually removed, or if the reacting substances can penetrate the barrier. In the oxidation of metals the rate of the reaction is almost entirely controlled by the rate at which metal or oxygen can penetrate the oxide layer. In general, as the oxide layer becomes thicker, the rate of reaction becomes slower. In some metals, notably aluminium, chromium and probably zinc below 225° C., oxidation stops altogether when the film has reached a thickness of the order of 10^{-6} cm., the protective film thus formed preventing further attack. The discussion of these protective films will be one of the chief purposes of this article.

Provided that one of the reacting substances can penetrate the oxide layer, we would expect that the primary process would be the formation of a fairly uniform film of oxide over the surface of the metal. In many cases, however, it seems certain that the oxide film breaks up as soon as it is formed, and recrystallizes in little islands scattered about the surface. The oxidation of zinc above 225° C. provides an example[1]. The oxide film shows a granular structure under the microscope, and does not show the interference colours obtained with compact oxide films on copper for example. Both facts point to the presence of a conglomerate of fairly large crystals of the type illustrated in Fig. 1(*b*) rather than a compact film. Electron diffraction experiments, moreover, reveal a well-defined crystalline structure.

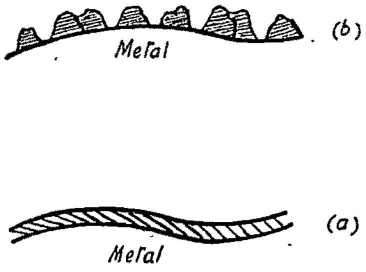

Fig. 1.

(*a*) A compact film and (*b*) a film that has undergone recrystallization.

The tendency of thin films on a substrate to recrystallize is well known, and is shown by the results obtained at Bristol by Appleyard[2], Lovell[3] and their co-workers on the conductivity of thin metal films evaporated on glass. Whereas it was found that by repeated degassing of the glass surface, and by depositing the metal at the temperature of liquid air, compact films of rubidium and cæsium could be obtained which would conduct electricity at a thickness corresponding to one or two atomic layers, other metals such as mercury, or alkali metals at higher temperatures, did not conduct until a thickness of about 500 A. was reached. It was concluded that the surface tension of the metal caused the splitting up of the film and its recrystallization in the form of crystals of about this size. Conductivity would begin when these islands were sufficiently numerous to be in contact with each other.

---

* Substance of a lecture delivered before the London Branch of the Institute of Physics on April 30.

Vernon and his colleagues found that the weight W of oxide formed on zinc followed the law

$$W = k \log (at + 1), \quad . \quad . \quad (1)$$

or, expressed as a relation between the rate of growth and W,

$$\frac{dW}{dt} = ka.e^{-W/k} ;$$

a was of the order 0·5 (hr.)$^{-1}$. A law of this type gives a rapid initial rate of growth which later becomes vanishingly slow. For example, after 200 hours W will be $2k$, but will reach the value $4k$ only after 20,000 hours. Thus the thicker films must be quite impenetrable to metal or oxygen. The maximum thicknesses obtained are of the order 500 A., the same order as those at which the mercury films conduct. This thickness, however, and hence the size of the individual crystals, increases fairly rapidly as the temperature is raised, as we should expect.

The logarithmic law of growth can be derived on certain assumptions, of which the most important is that the rate of oxidation is proportional to the area of surface not already covered. For the proof the reader is referred to the original papers[4].

We turn now to the compact films formed on copper, iron, aluminium and so on. Two main types can be distinguished: those in which the parabolic law is obeyed, that is to say the weight, and hence the thickness of the film, increase as the square root of the time; so that

$$W = At^{1/2} ; \quad . \quad . \quad (2)$$

and those in which the film grows to a constant thickness d and then practically stops. The oxidation of copper at and above room temperature, of iron[5] above 200°C. and the reaction of silver with the halogens[6] are examples of the first class. The constant A, which determines the growth-rate, increases rapidly with temperature. The protective oxide films formed on such metals as aluminium, chromium and on stainless steels and zinc below 200° are examples of the second class. Here the thickness d which the film reaches seems to be relatively insensitive to temperature. (Experiments to establish this more definitely would be of great interest; the oxide film formed on aluminium at 600° C. in Pilling and Bedworth's work does not seem to be more than ten times heavier than that formed at room temperature. The former film had probably recrystallized.) An example of the second type of growth law is given in Fig. 2.

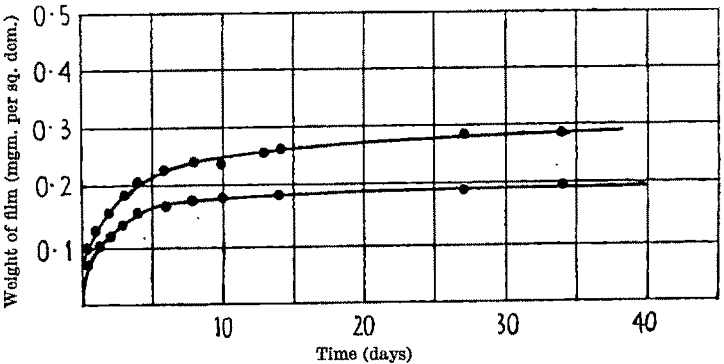

Fig. 2.

FORMATION OF ALUMINIUM OXIDE ON SHEET ALUMINIUM EXPOSED TO THE ATMOSPHERE AT ROOM TEMPERATURE (FROM W. H. J. VERNON, *Trans. Faraday Soc.*, 23, 113 (1927)).

The explanation of the parabolic law of growth was given some time ago by Tammann[7] and by Piling and Bedworth[8]. It is supposed that either the metal or the oxygen is soluble in the oxide. Let us suppose that the metal is soluble, the excess metal atoms going into interstitial positions in the oxide; then in the oxide in equilibrium with the metal there will be a certain concentration c_0 of excess metal atoms per unit volume. In the oxide film, however, while the reaction is in progress, there will be a concentration gradient of excess metal atoms, the concentration being c_0 at the oxide – metal interface, and zero at the free surface of the oxide, provided that the oxygen has pressure enough to react with the excess metal atoms as soon as they arrive. If x is the thickness of the film, the concentration gradient is thus c_0/x, so that the number N of excess metal atoms crossing unit area per unit time is given by

$$N = Dc_0/x,$$

where D is their coefficient of diffusion. But if Ω is the volume of oxide per metal atom, then the rate of growth dx/dt is equal to $N\Omega$; we thus have

$$\frac{dx}{dt} = \frac{D\Omega c_0}{x}, \quad . \quad . \quad (3)$$

which on integration gives

$$x^2 = 2\, D\Omega c_0 t ; \quad . \quad . \quad (4)$$

this is the required equation.

As equation (3) shows, the rate of growth for very small thicknesses becomes very great. We might expect then, in the initial stages of oxidation, especially at low pressures, that the oxygen pressure would not be sufficient to cause oxidation of the metal atoms as fast as they diffuse to the surface. In the initial stages of growth, then, we should expect a linear rate of growth. Wagner and Grünewald[9] have observed an effect of this type during the oxidation of copper at 1000° C. and a pressure of oxygen equal to that of 1 mm. of mercury. They found that until the film thickness had reached a value of the order 10^{-3} cm. the growth was linear, after which it followed the parabolic law.

We have next to consider whether, during the oxidation of any particular metal, the metal atoms move outwards through the oxide or the oxygen atoms or molecules move inwards. For the reaction of silver with (liquid) sulphur this has been settled experimentally in the following way[10]. Silver was separated from liquid sulphur by *two* slabs of silver sulphide, as shown in Fig. 3. After the reaction had been allowed to progress for some time, it was found that the upper slab II had increased in weight, but not the lower slab I. This shows that the silver diffuses through the sulphide and that the reaction takes place at the interface between the sulphur and the silver sulphide. If the sulphur were able to diffuse through the sulphide, the reaction would take place partly at the interface between the silver and its sulphide, and the weight of slab I would increase also.

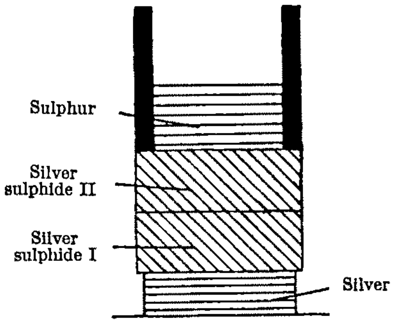

Fig. 3.

REACTION OF SILVER WITH SULPHUR.

In other cases conclusions may be drawn from the known properties of the oxides, especially from their electrical conductivities. The conductivities of oxides are in general due to the presence of small quantities of oxygen or of the metal constituent in excess of the stoichiometric composition, the excess atoms providing centres which lose an electron easily. The oxides of zinc and aluminium, for example, are what are known as reduction semi-conductors ; that is to say, their conductivity is increased by heating in a vacuum, when a small amount of oxygen is driven off and a corresponding number of metal atoms left behind, probably in interstitial positions. It does not seem possible, however, to produce these oxides with excess oxygen. We may reasonably assume, then, that the oxide film dissolves metal rather than oxygen, and thus that it is the metal ion which moves. An interesting consequence is that, for temperatures and oxygen pressures for which the parabolic law holds, the rate of reaction should be independent of the oxygen pressure for oxides of this type. This follows from equation (4) ; it will be seen that the reaction constant depends on the solubility of the metal only. However, as we shall see below, the parabolic law does not usually hold for this type of oxide.

Cuprous oxide, which is formed when copper is oxidized, is an oxidation semi-conductor ; that is to say, its conductivity increases when it is heated in oxygen, and is due to excess oxygen. There is evidence[11], however, that the oxygen is not taken up interstitially, the oxygen atom being too large to fit into interstitial positions in the oxide lattice. The way in which the lattice accommodates excess oxygen is through the absence from their normal lattice points of a few copper atoms. These vacant lattice points are mobile ; an adjacent metal atom can move into them, and then another atom will move into the position that has been left vacant, and so on. Thus in cuprous oxide also it is the metal atoms which move ; the vacant lattice points move inwards from the oxygen – oxide interface. In reactions of this type, the pressure of oxygen does have an effect on the rate of reaction, as has been shown for the case of copper by Wagner and Grünewald[9].

The oxides of iron form semi-conductors of the same type ; here the concentration of iron may have any value between those given by the formulae FeO and Fe_2O_3.

We do not know of any case of compact oxide films where it is established that the oxygen diffuses.

Wagner has suggested that the atoms diffusing through an oxide layer dissociate almost completely into ions and electrons. If the diffusion takes place through the motion of a vacant lattice point, then by dissociation we mean the following : If, for example, a Cu^{+} ion is missing, then a neighbouring Cu^{+} or O^{--} ion must have an electron missing, in order that the centre as a whole shall be electrically neutral. At high temperatures, however, the place where the electron is missing may move away from the vacant lattice point by a replacement process. It is suggested, then, that in cuprous oxide the vacant lattice points and the points from which an electron is missing (positive holes) are dissociated.

Estimates of the concentration of excess atoms and of the dissociation energy—the latter determined from the temperature variation of the conductivity of the oxide—enable a theoretical calculation to be made of the degree of dissociation, and the results bear out the hypothesis. More direct evidence has been obtained by Wagner[9] for the case of copper; he heated cuprous oxide at 1000° C. in oxygen until equilibrium was obtained, and measured the electrical conductivity; he found that it varied as $p^{1/7}$, where p was the pressure of oxygen. This is to be understood in the following way: each oxygen molecule gives two additional oxygen ions (O^{--}) in the Cu_2O lattice, and thus four vacant copper lattice points. If there were no dissociation we should expect the concentration to vary as $p^{1/4}$, if dissociation were complete as $p^{1/8}$, according to the law of mass action. The value obtained suggests that dissociation is nearly complete. As additional evidence, Wagner finds that the rate of oxidation of copper also varies as $p^{1/7}$.

We turn now to the consideration of the protective films formed on aluminium, chromium and other metals. The characteristic feature shown by these films is that they grow fairly rapidly up to a certain critical thickness, after which the growth is very small. The type of thickness-time curve is shown in Fig. 2. Various methods are available for determining the thickness of these very thin films. There is first of all the method of weighing before and during oxidation; this was used by Vernon to obtain the results shown in Fig. 2. To obtain the film thickness from the weight increase one must make an estimate of the true surface area of the surface area of an aluminium sheet. Erbacher[12] gives a ratio of 2·5 between the real and apparent surface, and using this factor we may deduce from Vernon's results a film thickness of 40 A. formed at room temperature. Steinheil[13] also obtained a thickness of 40 A. for the oxide film formed on aluminium after exposure to air for a few months by observing the progressive increase of transparency of evaporated aluminium films exposed to air. Tronstad[14] has used a polarimetric method to estimate the thickness, and gives the following table for films which have reached a constant thickness.

Mercury in dry air	15–20 A.
Aluminium in dry air	100–150 A.
Iron in dry air	15–40 A.
Austenitic stainless steel	10–30 A.

The crystal structure of the oxide films formed on aluminium has been examined by electron diffraction[15] using both reflected and transmitted beams; in the latter case the films were first stripped from the metal substrate. Very diffuse rings are obtained, suggesting that the films are built up of very small crystals. The films are thus to be contrasted with those formed by recrystallization, discussed at the beginning of this article, which give sharp rings. Another difference is that on aluminium, the maximum film thickness varies only slightly with temperature, whereas in the films formed by recrystallization the maximum film thickness increases very rapidly with temperature.

The present author has suggested a theory of the process responsible for the formation of these films[16]. This theory starts from Wagner's hypothesis that metal atoms diffuse through the oxide film in the form of metal ions and electrons separately. Since the films do not grow beyond a thickness of some 40 A. on aluminium, for example, it follows that either the ions or the electrons cannot pass through a thicker layer. It cannot, however, be the ions which find the difficulty, because oxide films thicker than 10,000 A. can be formed on aluminium by anodic oxidation[17], which shows that aluminium ions can pass through the layer if oxide *ions* are supplied at the surface.

It must, therefore, be the electrons which are unable to penetrate the thicker films. In oxide films which grow according to the parabolic law, one must suppose that electrons leave the metal and penetrate the oxide through a kind of thermionic emission; if an electron receives enough energy to leave the metal and move on to one of the metal ions of the oxide, it can jump from metal ion to metal ion and so on through the layer. We must suppose, however, that at the surface $Al-Al_2O_3$ the necessary work function φ is too great for this to happen up to 600° C., so that no emission will take place into a thick oxide film. This implies that $\varphi \geq 2$ ev. It is, however, possible for electrons to pass through a very thin film *without* receiving any energy of activation by what is known as the 'quantum mechanical tunnel effect'. According to the principles of quantum mechanics, it is possible for a particle to penetrate a small distance into regions of high potential energy for which, according to classical mechanics, its kinetic energy is insufficient. The principle has been used to explain, for example, the cold emission of electrons from metals in strong fields, and also the spontaneous α-decay of radioactive nuclei. The number of electrons per second penetrating a film of thickness x turns out to be about

$$10^{23} \quad e^{-4\pi x\sqrt{(2m\phi)}/h} \quad \text{cm.}^{-2}\ \text{sec.}^{-1},$$

giving a maximum rate of growth of the order

$$e^{-4\pi x\sqrt{(2m\phi)}/h} \quad \text{cm./sec.}$$

We may take the effective maximum film thickness to be reached when one atomic layer is added per year; for reasonable values of φ (1 to 2 ev.) this gives a thickness of 30–45 A.

We see, then, that when the oxide is a reduction semi-conductor, incapable of absorbing oxygen, the parabolic law of growth should be observed only if φ is not too large; if φ is large we get a protective film formed. On the other hand, if the oxide can absorb oxygen, the parabolic law will always be valid. Now it has been suggested on various sides[18] that reduction semi-conductors are oxides in which the metal ion has its maximum valency; and actually it appears that it is just oxide films of this type which are protective, namely, Al_2O_3, Cr_2O_3, ZnO. We have very little direct evidence[19] about the values that φ should have for metal - oxide interfaces, but it seems a not unreasonable assumption that φ is in general too large for thermionic emission. If this is the case we shall never get parabolic growth for this type of oxide, but always protective films less than 50 A. thick at low temperatures, and recrystallization leading to a logarithmic law of growth at high temperatures. For oxides such as Cu_2O, FeO, NiO on the other hand, the metal ion does not have its maximum valency, and the oxide can dissolve oxygen. Here we expect a parabolic law of growth producing a uniform film with interference colours. Recrystallization is not excluded for such films, but after it is complete the parabolic growth should continue.

The theory may also be applied to protective films on alloys. We have to note in the first place that protective oxide films can be formed at temperatures at which there is no possibility of metallic diffusion within the alloy. Therefore, when an oxide film is formed, both metals must enter into the oxide layer in the same proportion as that in which they are present in the alloy. That the constitution of the metal underneath the protective layer is the same as in the interior of the metal is also borne out by the fact that successive formations and removals of the protective films do not alter the capacity of the metal to form the films.

On the other hand, quite small additions of the second metal are sufficient to give considerable resistance to corrosion (for example, 7 per cent of aluminium in iron[20], or 3 per cent of aluminium in copper at 800° C.[21]). It is unlikely that 7 per cent of aluminium in ferrous oxide would be sufficient to alter the work function φ of the oxide - iron interface sufficiently to prohibit the passage of electrons. We therefore suggest that initially a mixed oxide is formed, but as the film thickens, the part of the film next to the metal becomes rich in aluminium (or chromium in chromium steels) until it becomes impervious to electrons, while an iron oxide film is formed outside it. The latter film is without influence on the protective properties.

The way in which this may be expected to happen is the following: so far we have considered the metallic ions as leaving the surface layer of the metal and moving in the oxide from one interstitial position to another until they reach the oxide - oxygen interface. Another process will probably occur at the same time; metal ions in an interstitial position will change places with metal ions in the oxide lattice. In an oxide of a single metal this process will not have any observable effect; but in the mixed oxide on steels the divalent ferrous ions will leave their lattice position with the expenditure of less energy than the trivalent aluminium or chromium ions. Therefore, in the layers next to the metal, the ferrous ions will frequently be replaced by the trivalent ions, while mainly ferrous ions will succeed in penetrating to the surface and forming new oxide layers.

It should be emphasized that our theory applies primarily to oxidation at low temperatures at which diffusion of one metal through the alloy is impossible. At high temperatures, on the other hand, it is possible that the proportions of the two metals in the oxide layer may be different from their proportions in the alloy. That this is the case is suggested by experiments of Iitaka and Miyake[22], who find that the protective films formed on copper - beryllium alloys containing one per cent of beryllium heated to a red heat give the electron diffraction rings characteristic of BeO alone. In order to explain these results, we may assume that diffusion within the metal takes place readily, and also that the beryllium ions diffuse through the oxide layer much faster than the larger copper ions, so that a protective film of BeO is formed before any appreciable amount of Cu_2O appears.

OBITUARIES

Sir Jocelyn Thorpe, C.B.E., F.R.S.

SIR JOCELYN FIELD THORPE died suddenly on June 10 at the White House, Cooden Beach, Sussex. For many years he has been an outstanding and distinguished personality in chemical circles. Born in London on December 1, 1872, he was the sixth son of Mr. W. G. Thorpe of the Middle Temple. He was educated at Worthing College, at King's College, London, at the Royal College of Science, and took a Ph.D. degree in organic chemistry under Victor Meyer at Heidelberg. In 1895 he became research fellow at Owens College, Manchester, where he remained for about fifteen years. Inspired immediately by the magnetic influence of W. H. Perkin, jun., his future career was clear—research was to be the alpha and omega of his life. Alone and jointly he published many papers on subjects which were to serve as the foundation for many of the modern developments in organic chemistry. For four years, from 1909, he transferred to Sheffield, continuing to work on the same subjects as Sorby research fellow of the Royal Society.

The expansion of the Imperial College at South Kensington gave the opportunity to create a full professorship of organic chemistry in 1914. Thorpe held this post until his retirement in 1930, during which period he steadily advanced his reputation for research and teaching: he trained a large number of brilliant students and did much to place Britain in the leading position in organic chemistry which it occupies to-day.

Thorpe's earliest work deals principally with the synthesis of various degradation products derived from the terpenes as well as with cognate problems of aliphatic and alicyclic chemistry; this was published partly with W. H. Perkin, jun. Thorpe was particularly interested in the glutaric and glutaconic acids and their stereochemistry; the latter acids especially provided him with an extremely fruitful field of inquiry, which he exploited to the full after leaving Manchester.

Thorpe's frequent use of ethyl cyanoacetate for synthetic purposes led him to investigate the structure of this compound, and eventually led to the work on the reaction which bears his name. During the Sheffield period he published many papers on the glutaconic acids and produced evidence supporting his "semiaromatic" formula for this compound. This formula, though later abandoned, has points of resemblance with the modern concept of a resonance hybrid and bears testimony to his originality and independence of thought.

After the War of 1914–18, Thorpe's research school underwent a rapid expansion and attracted an enthusiastic band of workers to the Imperial College. Numerous papers dealing with ring formation and with tautomerism appeared in the next few years, although Thorpe's name did not always appear in these memoirs; he left much of the field to his younger collaborators (Ingold, Kon, Farmer, Linstead) and encouraged them to make a name for themselves.

Thorpe's wide knowledge of and abounding interest in chemistry was perhaps the reason why he accepted the task of producing first a Supplement to the "Dictionary of Applied Chemistry" which bears the name of the other Thorpe (Sir Edward) and later a new edition, which is in course of publication. In this he has been assisted by Dr. M. A. Whitely, one of his most loyal colleagues over a long period of years. Thorpe's conception of this dictionary was on the most grandiose scale, and the effort to produce it must be prodigious.

Externally, Thorpe might have been taken for a country squire: he acquired certain little mannerisms which made him resemble what one might describe in the words 'an Edwardian aristocrat'. Actually he was a simple person and though highly cultured and many-sided in his interests, in the main he lived for his research and for the advancement of co-operative chemistry. He was the born committee man and enjoyed serving on these, though he was seldom assertive. Among Government committees he served on the Advisory Council of Scientific and Industrial Research (1916–22); on the Chemical Defence Committee, War Office; as president of the Indian Chemical Services Committee (1919–20); as a member of the Safety in Mines Research Board (1924–25); and as chairman of the Explosives in Mines Committee, Department of Mines, and as a member of the Dye-stuffs Development Committee, Board of Trade (1925–34). He was a member of almost every chemical committee and served as president of both the Chemical Society and the Institute of Chemistry. The former conferred on him the Longstaff Medal in 1921, and the Royal Society gave him the Davy Medal in 1922. He was made C.B.E. in 1917 and knighted last year.

Thorpe made a great effort to unite various chemical interests, and in particular to found a common meeting place in a Chemistry House, but the task proved too difficult. He was undoubtedly happy in his work, and though it may be said that he spread his energies and efforts too widely to leave him time to achieve outstanding success in any one thing, it is probable that his contribution to the common cause, so wholeheartedly and unstintingly given, has over many years had a profound effect in awakening the co-operative spirit among chemists, who perhaps are even more individualistic than the average citizen.

His many friends knew his sterling merits; he understood and appreciated the luxuries in life, was a wonderful host, collected china, possessed a fine chemical library. He was greatly assisted in all he did by his wife, née Lilian Briggs, whom he married in 1902.

E. F. ARMSTRONG.

Sir Thomas Hudson Beare

THOMAS HUDSON BEARE was born at Adelaide, South Australia, on June 30, 1859, and was educated at Prince Alfred College and the University of Adelaide. After obtaining the B.A. degree he was awarded the Fife (Australia) scholarship, and he then proceeded to London, where he studied at University College and obtained the B.Sc. degree of the University of London.

Before leaving Australia, Hudson Beare held an appointment in the Public Works Department, and was engaged on railway construction, and after completion of the London degree he had further practical experience in the Midlands and in Manchester.

In 1884 he was invited to join the staff at University College, London, and for three years assisted Prof. A. B. W. Kennedy in teaching and in private professional work. In a testimonial written in his favour at the end of that period, Prof. Kennedy commented on his ability as a teacher and an organizer, on his knowledge and skill as an engineer. Shortly afterwards, Hudson Beare was appointed to the chair of mechanics and engineering in the Heriot-Watt College, Edinburgh. He was the first occupant of this chair, and in two years he built up a most successful department.

In 1889, on the resignation of Prof. Kennedy, he was appointed to the chair of engineering at University College, London, and was very largely responsible for the planning and equipment of the new Engineering Department which was built in 1895. During this period, in addition to his normal duties, he was able to carry out a considerable amount of research work, and was awarded the Telford Premium by the Institution of Civil Engineers for a valuable paper on "The Building Stones of Great Britain". As a member of the Research Committees on Steam Jackets and on Marine Engine Trials, he published several papers in the *Proceedings* of the Institution of Mechanical Engineers.

In 1901 Hudson Beare was appointed regius professor of engineering at the University of Edinburgh. The Engineering Department of that time was small, poorly equipped and very inadequately housed, but under Hudson Beare's energizing influence the number of students rapidly increased, and in 1905 the Department was accommodated in new and well-equipped premises. So successful was he that the Edinburgh school attracted students from all parts of the Empire, from the Continent, from China and South America, and it was again found that the accommodation was inadequate. Once more Sir Thomas undertook the design of new laboratories, and in 1931 the Department was transferred to the Sanderson Engineering Laboratories at King's Buildings.

In 1913 Sir Thomas was elected dean of the Faculty of Science at Edinburgh, a post which he held until his death on June 10 last, and his expert knowledge and great administrative ability enabled him to render invaluable service to the University. For many years he was convener of the Works Committee of the University Court, and carried the enormous responsibility of supervising the erection of many new departments and of the many alterations required to adapt the older buildings to modern requirements. In 1908 he was appointed convener of the Military Education Committee of the University, and his keen interest in military affairs was largely instrumental in raising the Edinburgh University contingent of the Officers Training Corps to its high state of efficiency. He also represented the University as a member of the City of Edinburgh Territorial and Air Force Association, and for a period acted as chairman.

Sir Thomas acted for several terms as vice-president of the Royal Society of Edinburgh, was vice-president of the Board of Governors of the Edinburgh and East of Scotland College of Agriculture from 1932, chairman of the Board of Governors of the Royal (Dick) Veterinary College from 1923, and for many years a governor of the Heriot-Watt College. In 1921 he was appointed by the Secretary of State for Scotland as an assessor on the Central Miners' Welfare Committee, and served on the Commission until the time of his death. His knighthood was conferred upon him in 1926, and ten years later he received the honorary degree of LL.D. from the University of Edinburgh. He was a member of the Institution of Civil Engineers, a member and later an honorary life member of the Institution of Mechanical Engineers, and a member and vice-president of the Institution of Structural Engineers. He was a justice of the peace and Deputy Lieutenant of the County of the City of Edinburgh.

A man of outstanding ability, Sir Thomas's interest lay not in himself but in the work which came to his hands. In the later period of his service his many administrative duties compelled him, of necessity, to give up research work but never prevented him from keeping closely in touch with the latest developments in engineering. Throughout all the years he was able to continue his clear and logical teaching in his own department. Keenly interested as he was in students and in all their activities, it is not surprising that he won their regard and confidence, and this was reflected in the close associations they maintained with him in after-life. He was not merely a teacher of engineering and a great figure in the profession to which they belonged, but also one who inspired them with a sense of conscientiousness, of honour and of integrity in the carrying out of the duties of life. During these almost incredibly busy years relaxation was found in travel and in the study of Nature, but even in recreation his alertness of mind asserted itself, and he was accepted by entomologists as an authoritative specialist on the systematics of the Coleoptera.

J. B. TODD.

Dr. Matthew Young

WE regret to record the death of Dr. Matthew Young, anatomist and anthropologist, which took place on May 25 at the age of fifty-six.

Matthew Young was born in Ayrshire and educated at Kilmarnock Academy and the University of

SHORT REVIEWS

AGRICULTURE AND FORESTRY

A Text-Book of Agriculture

Designed for use in East African Schools. By J. G. Brash. Pp. xv+311. (London: The Sheldon Press, 1939.) 4*s*. 6*d*.

THE writing of a text-book of agriculture in English for use by a body of students whose knowledge of English is very meagre is surely a most difficult task. This is evidently realized by the author of the present book, for he includes a glossary not only of technical terms but also of words and expressions commonly in use in ordinary English. But if the task of preparing such a text-book must be faced, we have seen no attempt which attains a greater measure of success than that now under consideration. Apart from the language difficulty in the present case, there is another, which is referred to in the author's foreword, namely, that the pupils for whom it is designed look upon the study of agriculture in the schools as a disagreeable necessity, for most of them join the higher schools chiefly for the purpose of gaining a higher social status by getting remunerative employment on the completion of their school courses, and hence are in most cases only interested in those subjects which are required for such paid positions as are available to them.

Yet, in a country of which the whole economic future depends on agricultural progress, the latter must chiefly come through the younger generation who are now in the schools. It would seem, therefore, that if these young people are really to be weaned from the desire for mere clerical positions to a genuine devotion to the improvement of agriculture, there must be text-books which are of exceptional interest, and also inspiring teachers of the subject in the schools. Without the latter, the text-book will do little: with them, it would not be easy to prepare a better book than that under review.

In it, the principles of agriculture as applied to East African conditions are admirably presented, with emphasis on those matters which have proved to be the most important for the development of the country. Special features are the very lucid account of erosion and the methods of combating it, and a useful chapter on the co-operative organization of agriculture as it can be developed in East Africa.

The book can be highly recommended. It does almost all that a text-book can do in connexion with agricultural teaching in East Africa, but neither it nor any other text-book can direct interest and attention back to agriculture in the absence of an inspiring teacher. If the latter is there, then the book will be found of great value. H. H. M.

Timber

Its Properties, Pests and Preservation. By Dr. F. Y. Henderson. Pp. 186+19 plates. (London: Crosby Lockwood and Son, Ltd., 1939.) 9*s*. 6*d*. net.

NUMEROUS technical publications have been issued which deal separately with different aspects of timber technology, but none has appeared in Great Britain in which a general elementary account of timber in non-technical language is given. The book under notice, written primarily for students of engineering and building science, fills this gap. The text covers briefly the whole general field of timber technology as indicated under its sub-titles, and is profusely illustrated with line drawings and photographs, the majority of which are original. The style is refreshingly simple and straightforward, thus bearing the hall-mark of an author who not only knows his subject, but also has the gift of being able to put himself into the position of the student and general reader who is taking up the subject for the first time.

This book should prove of great value not only to engineering and building students, but also to the general public, all of whom are users of timber. In war-time it is important that the most economical use be made of our timber resources, and it is only through knowledge of its properties that it can be used most profitably. It is unfortunate that the price may put this book out of reach of many, but this is doubtless due to the general rise in cost of production, but to those who can afford it the nine shillings and sixpence should prove an excellent investment. K. ST. G. C.

Soil Analysis

A Handbook of Physical and Chemical Methods. By C. Harold Wright. Second edition. Pp. x+276. (London: Thomas Murby and Co.; New York: D. Van Nostrand Co. Inc., 1939.) 12*s*. 6*d*. net.

THE first edition of this book, although written particularly for those who have not the facilities of a good library, proved a useful addition to the bookshelves of most agricultural chemists. In this revised edition the author has replaced methods of analysis that were becoming out of date or of only minor importance by new ones. Some fresh sections have been added dealing with the freezing point, glass electrode, inorganic soil colloids and methods for the determination of cobalt and zinc. To the section on carbon the Ter Meulen dry combustion method has been added, together with a summary of the report of the Organic Carbon Committee of the International Society of Soil Science. This Committee compared a number of methods for determining carbon in soils, and the results and experiences of the analysts should be useful to soil chemists.

In presenting the chemical methods of analysis in his book the author has divided them into general and special methods, but the reviewer suggests that this grouping is not entirely satisfactory, since the ordinary Kjeldahl method for nitrogen and common methods for carbon are to be found under special methods, whereas the determinations of phosphoric acid and potassium appear in the general class. This is only a very minor criticism, and in no way detracts from the value of the book.

R. G. WARREN.

ANTHROPOLOGY AND ARCHÆOLOGY

James George Frazer

The Portrait of a Scholar. By R. Angus Downie. Pp. ix+141. (London: Watts and Co., Ltd., 1940.) 5*s*. net.

THIS "portrait of a scholar" is drawn by one who now for a number of years has been associated with Sir James Frazer's work. That association has been fruitful in producing the supplementary volumes of "The Golden Bough" and "Totemism", as well as the five volumes of selected extracts from the notebooks which bear testimony to the life-long and unremitting industry which Sir James has devoted to the commendable practice of note-making. A further outcome of this association is that it has given Mr. Downie an acquaintance, intimate and unrivalled, with the lines of every branch of investigation upon which Sir James has brought his genius to bear, as well as a clear insight into the working of his mind, so far as that is possible when dealing with a subject who both as an individual and as author exhibits in a supreme degree the scholar's qualities of balance and restraint.

Sir James Frazer's life-history is the story of his work; and he lives in his books. For the benefit of those who may know but little of that work, who perhaps have come into touch with only one aspect of it, or indeed may not know it at all, Mr. Downie has sketched a portrait of a many-faceted mind, and of what, had Sir James been a man of action, would have been termed justly a life of adventure in many fields. For in the realms of the mind Sir James has been a traveller in many remote tracts and untrodden ways, a pioneer and explorer in the dark ways of humanity. Chapter by chapter, Mr. Downie guides the reader, assisting his steps with illuminating quotation, from Sir James's early work at Cambridge and his association with Robertson Smith to "The Golden Bough", to "Totemism" and to "The Folklore of the Old Testament", to name the more important only among his monumental contribution to the comparative study of the human mind, its beliefs and the institutions to which it gives rise. But these, though the best known, do not complete the tale of his activities. In addition, there are the classical studies by which he first earned his right of entry to the learned world and produced his "Pausanias" and the "Fasti" of Ovid, border-line works; and there are also those purely literary studies of Cowper and Addison and the other 'pieces' in which some hold Sir James has risen to the highest point of that stylistic excellence which Mr. Downie rightly stresses throughout.

The Illusion of National Character

By Hamilton Fyfe. Pp. v+274. (London: Watts and Co., 1940.) 8*s*. 6*d*. net.

MR. HAMILTON FYFE sets out to destroy the generalizations about peoples—mainly the illusion of national character—which in past and current discussion obscure counsel. While some generalizations about large groups are possible, is it true that general statements about Englishmen, Frenchmen or Germans are valid, apart from affirmation of such externals as membership of a particular State, geographical habitat or language? Is there over and above these such a thing as national character? As will be gathered from his title, in the judgment of the author there is not. Even though he is prepared to concede certain differences due to surroundings, he would maintain that, beneath, these peoples are alike. On this it may be remarked that while this may be true of race in a biological sense and the so-called 'racial theory' a delusion, when it is not a fraud, national character stands in a different category. The cumulative effect of cultural continuity, viewed historically, cannot be ignored; any attempt to do so will be no less disastrous than the exaggerated nationalism which has brought about the War.

BIOLOGY

Graptolithina

Von O. M. B. Bulman. (Handbuch der Paläozoologie, herausgegeben von O. H. Schindewolf, Lieferung 2, Band 2D.) Pp. iii+92. (Berlin: Gebrüder Borntraeger, 1938.) 13 gold marks.

THIS is the first part to be published of a comprehensive treatise on palæozoology. The general plan is similar to that of Zittel's great "Handbuch" (1876–93), but whereas that work was in four volumes and, with the exception of the parts on Insecta and Myriapoda, was written entirely by von Zittel, this new work is to consist of twenty volumes by nearly fifty specialists.

In this part, Dr. Bulman gives a masterly account of the Graptolithina. Each of the two main divisions, the Dendroidea and the Graptoloidea, is considered under the headings: diagnosis, morphology, development, ecology, distribution, phylogeny and systematics. There is no separate section on the history of the subject, but the development of knowledge is indicated in each section of the work. The illustrations are numerous, and those showing morphology and development are especially noteworthy. In the systematic part diagnoses are given of all the known genera. It is to be regretted that the outstanding work of Kozlowski could only be considered briefly in a postscript. His discovery in the Upper Tremadoc, south of Warsaw, of the most perfectly preserved Dendroids yet known has led him to the conclusion that the Graptolites are not hydroids, but are closely related to the Pterobranchia among the Hemichordata. This is supported by the presence among the Graptolites of a Pterobranch allied to the living Cephalodiscus.

Elementary Microtechnique

By H. Alan Peacock. Second edition. Pp. viii + 330. (London: Edward Arnold and Co., 1940.) 9*s*.

REASONABLY priced, compact, well bound and clearly written, this book surpasses the high standard already set by the author in the first edition. There are chapters on the microscope and its use, methods of making preparations of animal and plant tissues, methods of wax-embedding, formulæ, sources and culture of material, preservation of material, etc.; while more than a hundred pages are devoted to methods of dealing with specific material, both plant and animal. There are also an excellent little bibliography and a list of dealers from whom amateurs or schools not favourably situated can obtain enough to satisfy the most exacting student of the microscope. The author has done well to set out his practical instructions line by line in numbered sequence, adding the length of time for applying each reagent and giving a number of alternative methods. For the next edition, the author should consider omitting the chapter on the protoplasm and the cell (too short to be of great use) and substitute a few pages on the cultivation of microscopic fungi, with details of various nutrient media in common use. All students and teachers of biology owe thanks to Mr. Peacock for this excellent little compendium; for its scope there is none better.

Food Values at a Glance

And How to Plan a Healthy Diet. By Violet G. Plimmer. Second edition. Pp. 190. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1939.) 6*s*. net.

MODESTLY disclaiming any expert knowledge of nutrition, Mrs. Plimmer has launched the second edition of this useful little work at a time when, as she herself puts it, there is opportunity to recast and modernize our defences on the food front. Her disclaimer is misleading if by the knowledge of nutrition we understand a knowledge of how properly to nourish the body, because here are all the essential facts clearly presented and in very readable form. Although I do not think every reader will find Mrs. Plimmer's "Neapolitan Ice" method of portraying the composition of foods as convenient to refer to as the more customary tables, it at least lends colour to the commonsense account she gives of up-to-date views on diet in relation to health and fitness. At a time such as the present this handy little work should be widely read. J. C. D.

The World of Insects

By Prof. Carl D. Duncan and Prof. Gayle Pickwell. Pp. ix + 409. (New York and London: McGraw-Hill Book Co. Inc., 1939.) 21*s*.

THIS book is one of the best elementary manuals on insect life that has appeared during recent years in the United States. It is well adapted for the general reader or the student-beginner, since technicalities are reduced to a minimum and the subject is attractively presented without a noticeable tendency to be unduly popular. While sufficient grounding in structure and classification is given, the book, in the main, is concerned with living animals, and more attention is shown to such matters as life, growth, behaviour, food, locomotion, etc. There is also a useful chapter on injurious insects and the means for their control. The illustrations are very good and original, and comprise both line and half-tone examples. Many of the latter are really effective results of the expert use of photography.

Calluna

A Monograph on the Scotch Heather. By W. Beijerinck. (Verhandelingen der Koninklijke Nederlandsche Akademie van Wetenschappen, Afdeeling Natuurkunde, Sectie 2, Deel 38, No. 4.) Pp. 180 + 30 plates. (Amsterdam: N. V. Noord-Hollandsche Uitgevers Maatschappij, 1940.) 7.50 fl.

IN view of the great importance of Calluna in diverse types of vegetation, a monograph, which aims at bringing together all that is known about this plant, will be very welcome to the ecologist. The author has sifted a large volume of literature and, where needful, has supplemented available information by his own investigations so that information on a wide diversity of topics is provided. Considerable space is devoted to a consideration of external and internal structure, as well as of the life-history, and this is copiously illustrated. Occasional points are obscure; for example, it is difficult to follow the data on cork-development on p. 34. On the ecological side the monograph falls a little short of the ideal. Thus, there is but little information on such topics as rooting depth, seedling mortality, and regeneration after fire, while the British reader would no doubt seek more data than are afforded on the vegetation-types in which Calluna plays a part. The subject-matter is well arranged, but for a treatise of this size some kind of index would have been desirable. F. E. F.

ENGINEERING

The Engineer's Year-Book of Formulæ, Rules, Tables, Data and Memoranda for 1940

A Compendium of the Modern Practice of Civil, Mechanical, Electrical, Marine, Gas, Aero, Mine and Metallurgical Engineering. Originally compiled by H. R. Kempe and W. Hanneford-Smith. 46th annual issue, revised under the direction of L. St. L. Pendred. Pp. lxi+xii+2788. (London: Morgan Brothers (Publishers), Ltd., 1940.) 31*s.* 6*d.* net.

SUBSTANTIALLY the same publication in the form in which it has appeared for a number of years, "Kempe's Engineer's Year-Book" has been issued in its 1940 edition. Though once again in its forty-six years' history it has been published in time of war, this fact has not changed its form or restricted the great range of the information it presents. A few changes there have been, but these are in the nature of those developments which must necessarily take place in a work of this kind in order to keep it up to date and to maintain its usefulness at a maximum. The section dealing with the costs of engineering works has therefore been excised, for at the time of preparation it was apparent that the prospects of war negatived its value for so long as conditions should remain abnormal. The space thus released has been occupied with some of the mathematical tables which were discarded a few years ago so that the bulk of the volume might be limited.

The original aim of its first editor to produce a work which, being carefully brought up to date, shall take its place as the standard book of reference in the profession is fully maintained in the latest issue. The list of associate editors and contributors, forty-six in number and each responsible for the preparation of a section, contains the names of recognized experts, most of them engineers, and the section dealing with timbers has been revised by the Forest Products Research Laboratory. The user can therefore feel fully confident that the information given throughout its pages is in the highest degree reliable. In a way, it appears at a psychological moment, for with the whole engineering profession of Great Britain organizing itself for its duties in the War, and its members engaged in new work, the need for such a work of reference is greatly enhanced.

The Engineers' Manual

By Prof. Ralph G. Hudson. Second edition. Pp. iv+340. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 13*s.* 6*d.* net.

PROF. HUDSON'S book contains what may be regarded as the 'permanent information' of engineering. It comprises a consolidation of the principal formulæ and tables of mathematics, mechanics, hydraulics, heat and electricity in frequent use by practising engineers and engineering students. As each set of formulæ is preceded by a statement giving its application, the physical quantities involved and the units of measurement used, the appropriate formula is quickly selected and accurate substitution readily effected. The sequence in which the formulæ are arranged is, so far as possible, that of the order of derivation, so that, where it may be required, the source of any statement can be recognized from an inspection of those immediately preceding it.

GEOGRAPHY AND TRAVEL

The Scenery of Sidmouth

Its Natural Beauty and Historic Interest. By Dr. Vaughan Cornish. Pp. xiii+86+6 plates. (Cambridge: At the University Press, 1940.) 7*s.* 6*d.* net.

NO one has raised his voice more frequently or with greater sincerity for the preservation of the beauties of rural England than Dr. Vaughan Cornish. To him, as indeed to many others, the charm of our English countryside is one of the priceless heritages of the land, and he says with truth that sorrow is softened and hope strengthened by the peaceful beauty of rural England. In earlier works Dr. Cornish has tried to establish general principles for the æsthetics of scenery. In this small book he illustrates these principles by the analytical description of a small area. The corner of South Devon he has chosen is one of long family associations; and he has been able to give practical expression in it to his desire for preserving beauty in saving the valley of Salcombe Regis from spoliation by the builder. It is a charming volume, which shows the mingling of scientific spirit and æsthetic appreciation in the manner that the author has made all his own, and it provides at very least an hour or two of soothing comfort in these dire days. There are charming illustrations and an excellent map.

The Statesman's Year-Book

Statistical and Historical Annual of the States of the World for the Year 1940. Edited by Dr. M. Epstein. Seventy-seventh annual publication: revised after Official Returns. Pp. xxxviii+1488. (London: Macmillan and Co., Ltd., 1940.) 20*s.* net.

EVEN in these difficult times this annual statistical review of the world appears, not merely with regularity, but also with all its usual features and at the usual price. The task of revision has presented many obstacles, and for several States the discontinuance of official statistics has been a drawback. Yet the picture of the world in the opening quarter of this year is wonderfully complete. States now in enemy occupation appear in their rightful places: thus Poland, and Danzig, as well as the later occupied western States, retain their nominal independence. Czechoslovakia and Albania also have their places, but Ethiopia is submerged. Even the League of Nations still figures, but the list of non-members is now a long one. The useful introductory tables give world production of petroleum, cotton, iron and steel, gold and rubber. A coloured folding map shows the extent of the U.S.S.R. with indications of the various degrees of autonomy, 'protection' and influence attributed to the different constituent States and territories.

GEOLOGY

A Descriptive Petrography of the Igneous Rocks

Vol. I: Introduction, Textures, Classifications and Glossary. By Prof. Albert Johannsen. Second edition. Pp. xxiv+318. (Chicago: University of Chicago Press; London: Cambridge University Press, 1939.) 27*s*. net.

THE publication of Prof. Johannsen's four-volume "Petrography" was completed by the appearance of the last volume in 1938. Notices of the work have appeared in NATURE, **129**, 636 (1932); **132**, 691 (1933); and **142**, 495 (1938). The first volume, dealing mainly with the textures and classification of the igneous rocks, now appears in a second edition.

In his preface to this new edition, Johannsen quotes a statement made by Tom Barth in connexion with certain proposed modifications of rock classifications: "One should always be careful not to spoil a good idea by undue improvements". Apparently adopting this advice, Johannsen has made very few alterations in his revision. Apart from a few minor improvements of the text and additions to the biographies of prominent petrographers, he has been content to make only the following changes. The summary of Hodge's quantitative system of rock classification has been replaced by short accounts of Lacroix's (1933) and Tröger's (1935) systems. A few pages are added dealing with Niggli's (1931) modification of Johannsen's classification and with Andreatta's (1937) modification of Niggli's modification; these few pages are headed with a figure of what appears to be a monkey-wrench—a pleasant gibe which most readers will appreciate. A new appendix, giving the definitions of some 750 rocks described in the other three volumes of the work, has been added, but the other appendixes and tables remain exactly as in the 1931 edition. Teuscher's (1933) method of describing granularity is summarized, and Fersmann's (1928) views on the origin of graphic texture are briefly mentioned. With the exceptions noted, no reference to new work appearing since 1931 is made.

Das Relief der Erde

Versuch einer regionalen Morphologie der Erdoberfläche. Von Prof. Dr. Fritz Machatschek. Band 1. Pp. xi+545+10 plates. (Berlin: Gebrüder Borntraeger, 1938.) 36 gold marks.

NOTWITHSTANDING the title of his great work, "Das Antlitz der Erde", Suess really provided the classic account of the skeleton of the earth's crust. Machatschek proposes to describe the true face of the earth, and to discuss the geological factors that have controlled its development. The whole work will exhibit the relations between the single physiographical units of the earth's surface and the geological-tectonic raw material from which they have been derived. It will be a study in morphotectonics.

This first volume here noticed begins with a few pages of introductory matter, dealing mainly with the classification of the major divisions of the earth's surface. Then follows a treatment of the continental block of Europe and Asia, that is, the part of these continents lying north and west of the Alpide fold-zones. The units of the British Isles, Middle Europe, Fennoskandia, Russia, Siberia, Central and East Asia are dealt with in turn. As an example of Machatschek's method, we may take his account of Fennoskandia; brief summaries of the Pre-Cambrian and Caledonian history are followed by a detailed description of the glacial and post-glacial happenings, and this by a discussion of the topography special to the dozen separate districts into which he divides the region. The second part of the volume deals with the Alpide fold-belt in Europe and North Africa, and treats of the Mediterranean countries.

There are 141 text-figures, many being morphological maps, and ten excellent morphotectonic plates which cover most of the greater regions of Eurasia. The bibliography is selected. The book is good meat for geologists and for those geographers blessed with some geological knowledge.

MATHEMATICAL AND PHYSICAL SCIENCES

The Cyclotron

By Dr. W. B. Mann. (Methuen's Monographs on Physical Subjects.) Pp. xi+92. (London: Methuen and Co., Ltd., 1940.) 3*s*. net.

THE cyclotron is essentially an instrument acting as a source of very high velocity nuclear particles—protons, deuterons, neutrons and alpha-particles—which have been used successfully by physicists in the further study of the constitution of matter by atomic bombardment. Although the fundamental principles of the method were known more than ten years ago, it is during the past few years that the problems involved in the design and construction of practical apparatus have been solved by the work of E. O. Lawrence at the University of California, Berkeley. The author of this little monograph, Dr. Mann, spent a period of two years in Prof. Lawrence's laboratory, and so has been able to describe the principles and some of the possibilities of the cyclotron, as the result of first-hand experience.

After an introductory chapter, a description is given of the phenomenon of magnetic resonance acceleration, upon which the operation of the cyclotron depends. Details of the design of the cyclotron vacuum chamber and the associated magnet are then given, followed by somewhat less satisfactory chapters on the radio-frequency supply, and the adjustments and electric and magnetic focusing arrangements involved. The final chapter, entitled "Applications of the Cyclotron", would appear to be unnecessarily detailed, and much of the material discussed is not concerned with the cyclotron as such but rather with atomic physics and chemistry. This account could have been made more interesting to the general scientific reader, for whom this series of monographs is intended, by confining the description to a few examples, treated more generally. A good bibliography is included at the end of the book.

Advanced Calculus

By Prof. Ivan S. Sokolnikoff. Pp. x+446. (New York and London: McGraw-Hill Book Co., Inc., 1939.) 26*s*.

THE preparation of a book on advanced calculus always entails some difficulty, for, on one hand, essential rigour must not, at this stage, be sacrificed, while, on the other, the course must be sufficiently concrete to appeal to the student and especially to the practical student. There is no doubt that interest in mathematics is often thwarted by a too rigorous presentation of analytical doctrine, and yet even practical students must assimilate an irreducible minimum of valid theory in order to make an intelligent use of mathematics. With these thoughts in mind, it is interesting to turn to Prof. Sokolnikoff's new volume. In the preface, the author admits that the subject is far from easy, but lays down the unalterable aphorism that the solving of problems "is essential to a mastery".

The ideas the basis of which lies in geometry are presented intuitively, whilst proofs of many academic theorems, like those on convergence of monotone sequences; those of Bolzano-Weierstrass, Darboux and a few others, have been wisely omitted, although references to other treatises, where proofs may be found, are given. One very commendable feature lies in the fact that the author has relegated no difficult or essential proof to the exercises provided for the student's practice.

The course embraces the usual topics dealt with in what is generally known as advanced calculus. It begins with limits and continuity; derivatives and differentials; then passes to a full consideration of integration—including definite, multiple and line integrals, and, after two chapters on series, improper integrals. Finally, Fourier series and a simplified formal treatment of some of the important problems arising from the theory of implicit functions are discussed.

The text is written with clarity and is well illustrated both by diagrams and exercises, worked and unworked.

Algebra for Science and Engineering Students

By E. H. Lockwood. Pp. ix+102. (Cambridge: At the University Press, 1940.) 6*s*.

THIS book has been specially prepared for secondary school pupils taking advanced courses in science and engineering. As the author points out, its essential feature is brevity, the aim being to present those parts of the so-called 'higher algebra' which are essential for sixth form pupils, on the science and engineering side, who do not offer mathematics as a main subject. The course begins with indices, logarithms and surds, then passes to variation; the theory of quadratic equations; factors and their development, including cyclic symmetry and partial fractions; permutations and combinations, leading to the binomial theorem for a positive integral index. The remaining part of the volume is devoted to the elements of simple probability, series and an introduction to statistics. A few practical applications of some of the principles explained in the text are given among the exercises provided for the student to solve.

The deliberate brevity of the treatment renders the text, particularly in the earlier chapters, almost a summary—and a good summary too—of the algebra needed for a sound training in what, a few years ago, would have been called the non-mathematical sciences, and, judging by the preface, the author has the biology student especially in mind, for he states: "Biology is becoming every day more mathematical." The treatment of the latter part on probability and statistics is much fuller and interesting, and should prove a welcome introduction to these subjects.

The book is certainly valuable for its purpose and is well illustrated both by line drawings and exercises to which answers are given. In the case, however, of engineering or physics, is not a full course in mathematics, taken to main subject standard, essential?

Electricity and Magnetism for Students

By S. R. Humby. Pp. 319. (London: John Murray, 1939.) 6*s*. 6*d*.

THIS excellent book is intended mainly for students who are preparing for entrance scholarships to the universities, and the Higher School Certificate and University Intermediate examinations, while it also covers a lot of the ground necessary for an ordinary degree. One of the many good features of the book is the flexibility of the treatment given, for as the author says in his preface, "Each chapter gives a complete, though necessarily limited, discussion of its part of the subject"; this means that the chapters may be dealt with in any order to suit requirements, and though in the book the work on electrostatics is separated from that on current electricity by the long chapter on magnetism, the author does not suggest that this sequence should be rigidly adhered to.

Mr. Humby has kept the needs of the students well in the forefront, and his courage in concentrating on one aspect of a theory which can be approached by several methods is to be commended, and will no doubt be greatly appreciated by students.

The author claims to have made a special effort to resolve the difficulties of magnetic induction, and it must be said that the skilful way in which he has developed this theory in the same chapter as other magnetic phenomena, instead of making it appear more formidable by devoting a separate chapter to it, seems to have justified his claim. Another pleasing feature is the logical sequence adopted in connexion with conduction of electricity, the conduction in solids, liquids and gases being dealt with in successive chapters.

Altogether it is an up-to-date book, well produced on very sound lines, and it should be found very helpful by students.

Household Physics

By Walter G. Whitman. Third edition. Pp. vii+436. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1939.) 18*s.* net.

THIS book, now in its third edition, deals with the practical applications of physics with particular reference to the home. The general plan of the first edition has been retained, but many changes have been made and six new chapters have been added, including one on air-conditioning.

Throughout the book the everyday experiences of students are used as a base from which to develop the concept of the fundamental laws of physics; there are twenty-eight chapters embracing examples in all the main branches of the subject, and since the whole is so comprehensively treated, the author has found it impossible to give great detail. Many very clear diagrams are included, and at the end of each chapter a useful summary of the main points is given, also a few suggestions for further study.

The book will provide interesting and instructive reading to both boys and girls, whether they are proceeding to a more academic treatment of the subject or not, and certainly a greater knowledge of the underlying principles and the operation of many devices found in the modern home will be of benefit to all. The student must be warned, however, that in some cases the author has been compelled, owing to lack of space, to give a necessarily condensed and incomplete theory; this is sufficient for ordinary purposes, but the student who is interested in pure physics will wish to go more deeply into such theory.

MISCELLANY

Acute Infectious Diseases

A Handbook for Practitioners and Students. By Dr. J. D. Rolleston and Dr. G. W. Ronaldson. Third edition, revised and enlarged. Pp. ix+477. (London: William Heinemann (Medical Books), Ltd., 1940.) 17*s.* 6*d.* net.

THE third edition of Rolleston's work, now under dual authorship, maintains the high standard of previous editions. The book is well produced, and, considering the amount of information supplied, is very convenient to handle. The absence of clinical illustrations, to which reference is made in the preface to the first edition, is amply compensated by the graphic description given of the cutaneous lesions of the acute exanthemata. It is unusual in a work of this size to find an attractive historical summary of each disease and also a serviceable bibliography. The source is a guarantee of scholarship and accuracy.

At a time when infectious diseases are specially liable to occur, the publication of such a book is opportune, for it offers to all, whether in the Services or in civilian practice, a reliable guide on all matters of treatment and prevention. Since the publication of the last edition, chemotherapy has revolutionized the treatment of certain infectious diseases, the use of serum in treatment and prevention has been extended, and much work has been done with regard to immunization, more especially in the virus diseases. All these subjects have received a detailed consideration which will be of value to the practitioner. Two additional chapters deal with erysipelas and isolation methods. The former is opportune as erysipelas is an excellent example of a disease amenable to both serum treatment and chemotherapy. The last chapter, with plans of modern isolation blocks, will appeal to all who are interested in administration.

The Annual Register

A Review of Public Events at Home and Abroad for the Year 1939. Edited by Dr. M. Epstein. Pp. xiv+507. (London, New York and Toronto: Longmans, Green and Co., Ltd., 1940.) 30*s.* net.

IT is seemly that an annual volume that now makes its hundred and eighty-first appearance should be published at the accustomed time and should maintain its normal size and all its normal features. As usual, more than half the volume is a review of world history with special regard to Great Britain and the British Empire. The year was one of preparation for war in most lands, but, as events have shown, a preparation that proved too leisurely even during the last four months of the year. Other European States receive full consideration, and the enigmatic attitude of the Soviet Union is revealing. The second part of the volume has the usual chronicle of events, obituaries and retrospect of art, science, literature and finance. The review of science directs attention to an unusually prolific year in biological publications and great advances in many aspects of that subject. Several important public documents are printed in full. They include the agreement with Poland, the treaty of mutual assistance between the United Kingdom, France and Turkey, the Russo-German pact and the various Soviet pacts with the Baltic States.

PHILOSOPHY

Causality and Science

By Prof. Nalini Kanta Brahma. Pp. 120. (London: George Allen and Unwin, Ltd., 1939.) 6*s.* net.

AS an ultimate assumption of science, the principle of causation is capable of a metaphysical analysis. Deploring the rejection of final causes by modern science, Prof. Brahma believes that the present interpretation of physics has not come to stay. For example, he questions that the indeterminism in the effect proves the indeterminism in the cause; and he contends that the idealistic view of physics is more superficial than fundamental. Moreover, scientific causality, whatever be its interpretation, is always partial, as it does not cover the other realm of values which give colour to life. The author rejects the mechanistic as well as the organic theory of causality. He holds that a cause is neither a sum total of conditions nor an implication of the whole effect latent in itself. For in both cases, causality lacks purpose, intelligent direction and plan, the essentials of real creativity. In order to account for heterogeneous variations, it is necessary to assume an absolutely perfect cause; in essence, a creative will. This conclusion, which is in line with the Hindu notion of change as illusory, brings us into the field of metaphysics. But the discussion of the various conceptions of causality is a valuable addition to the critique of scientific method and of its implications.

T. G.

Charles Peirce's Empiricism

By Dr. Justus Buchler. (International Library of Psychology, Philosophy and Scientific Method.) Pp. xvii+275. (London: Kegan Paul and Co., Ltd., 1939.) 12*s.* 6*d.* net.

DR. BUCHLER'S clear presentation of Peirce's empiricism is extremely welcome. Peirce was a fertile and original thinker of no mean order; his work is too little known in Great Britain, but Dr. Buchler's book should introduce it to English readers. The task could not have been easy. Peirce was unsystematic in his thinking and fragmentary in his writings. Nevertheless, he is worth the labour of piecing together his disjointed reflections. His contributions to symbolic logic are of permanent value, and his conception of methods of inquiry and of establishing beliefs forestall much of the work that we associate with the names of Carnap and Wittgenstein. This is a book to be recommended.

STATISTICS

Statistical Mathematics

By Dr. A. C. Aitken. (University Mathematical Texts.) Pp. vii+153. (Edinburgh and London: Oliver and Boyd, 1939.) 4*s.* 6*d.* net.

THE recent appearance of several works on probability and statistics within a short time may suggest that they must overlap and that the subject is receiving undue attention. But on the contrary, while they are a sign of widespread interest, they differ sufficiently in aim and treatment to make them supplementary in a genuine sense. The subject can be approached from different points of view, and it has enough vitality to make the day far distant when a single text-book will be found satisfying.

This little book is so excellent and at the same time so inexpensive that it should be added to their collections by all who are interested in the methods of probability. It is a marvel of compression, but it must be understood that this result is due partly to a judicious choice of topics and partly to the consistent use of a general method. Its leading feature, in fact, is the introduction of the generating function in its several most important forms. By this means Dr. Aitken has succeeded in combining elegance and brevity without sacrifice of lucidity, though the less instructed reader may still find a more leisurely and pedestrian line of approach more congenial at an early stage. The book is naturally devoted mainly to the principles of statistics, but space is found for numerical examples fully worked and even for some explanation of modern statistical technique.

Statistical Methods

For Medical and Biological Students. By Prof. Gunnar Dahlberg. Pp. 232. (London: George Allen and Unwin, Ltd., 1940.) 10*s.* 6*d.* net.

G. DAHLBERG'S new book will be a disappointment to those who appreciated his excellent book on twins (1926). Its aim, to present statistical methods in a form calling for no special knowledge of mathematics, but at the same time to give some idea of the concepts on which these methods are based, is practically the same as D. Mainland's "The Treatment of Laboratory and Clinical Data"; but, whereas Mainland gives detailed explanations of the tests of significance most frequently used, even the *t* test finds no place in Dahlberg's book. It is puzzling that it should be published in 1940. R. A. F.

Tables of Random Sampling Numbers

By M. G. Kendall and B. Babington Smith. (Tracts for Computers, No. 24.) Pp. x+60. (Cambridge: At the University Press, 1939.) 3*s.* 9*d.*

AN early publication of the Department of Statistics, University College, was Tippett's series of random sampling numbers (1927), regarded by many at first as a most eccentric sort of publication. With the introduction of randomization as an experimental precaution, this table was soon found to save a great deal of time, and many laboratories provided themselves, for their own use, with additional random series. The recent "Tract for Computers" contains a hundred thousand new numbers.

R. A. F.

Tests of Significance

What they Mean and How to Use Them. By John H. Smith. Pp. ix+90. (Chicago: University of Chicago Press; London: Cambridge University Press, 1939.) 6*s.* net.

J. H. SMITH'S pamphlet is an indication that the teachers of business administration, like those of psychology and education, are becoming aware of the modern movements of statistical thought. The treatment seems clear and sound, and the ground covered is no more than that needed by all students of statistics. R. A. F.

A Bibliography of the Statistical and Other Writings of Karl Pearson

Compiled by G. M. Morant, with the assistance of B. L. Welch. (Issued by the *Biometrika* Office, University College, London.) Pp. viii+119. (Cambridge: At the University Press, 1939.)

MORANT'S bibliography of Karl Pearson covers 648 items from 1879 to 1935. Short annotations are given in some cases, but for the student of the history of statistics these are too colourless to be helpful. The work is an unsparing labour of love.

R. A. F.

PRINTED IN GREAT BRITAIN BY FISHER, KNIGHT AND CO., LTD., ST. ALBANS

Glasgow, where he was trained as an anatomist by Prof. John Cleland, whose senior medallist and junior demonstrator he was. He graduated with honours M.B., Ch.B. in 1907 and was Brunton Memorialist of his year. After a year in private practice he became senior assistant to Prof. T. H. Bryce in his old University. In 1915 he received the Bellahouston and Struthers gold medals for his M.D. thesis on "The Scottish Skull", and was in the same year appointed by the Medical Research Council to work under the late Dr. John Brownlee on the stupendous task of compiling and analysing a case record and card-index of all officers and men admitted to hospital during the War of 1914–18. This work, which was not completed until 1922, involved the preparation and arrangement of 22 million index cards and the analysis of a million and a quarter medical case sheets. This material was taken over by the Ministry of Pensions.

Young continued on the staff of the Medical Research Council until 1927, when on the death of Dr. Brownlee and after taking the D.P.H. of Cambridge, he was transferred to the external staff and by a special arrangement was attached to Elliot Smith's department at University College, London, holding the position of lecturer in anatomy. This was perhaps the happiest and most fruitful period of his life. It gave him the opportunity he had long desired, to return to his studies in anatomy and anthropology, as well as of exercising his powers of statistical analysis, of which he had first given assured evidence in his thesis on the Scottish skulls, and had further demonstrated in statistical papers, some twenty in number, published during 1920–27 and including studies in epidemiology and the incidence and mortality of cancer. It has been said that Young's work substantially raised the standard of medical research in Great Britain by insisting on the proper biometrical treatment and interpretation of numerical data. Further, his work at University College in congenial surroundings gave full scope to those sound, if unobtrusive qualities, of which the most highly valued was his constant readiness to place his abilities and his profound knowledge at the service of colleagues and students alike. He was invited to join the committees of the Medical Research Council on dental disease and statistics. In connexion with the work of the former he published a study of the relation of dietary deficiency to dental disease, dealing with data collected in Birmingham under the auspices of the committees.

As anatomist and anthropologist, Young published numerous papers, perhaps half in collaboration with others; and it is no exaggeration to say that several of these of considerable value would never have been written had it not been for his encouragement and readily offered assistance. He was particularly interested in the problems of facial growth with reference to the development of dentition. One of his most important contributions to the subject was a study of the growth of face and jaws in children, which with other work gained him the D.Sc. of the University of Edinburgh. More directly anthropological studies were his collaboration with Sir Grafton Elliot Smith in the study of the London skull known as "The Lady of Lloyd's".

Mr. H. Higgs

Henry Higgs, who died on May 21, belonged to that type of economist of which John Stuart Mill was the leading example in an earlier generation, the economist public servant. Born in 1864, he entered the Post Office secretariat in 1884; was transferred to the Treasury fifteen years later; and served as private secretary to a succession of statesmen. He retired from the Treasury in 1921; was for a time lecturer in economics at Bangor and, for the ten years, 1929–39, was occupied mainly with work on the "Economic Bibliography", of which a first volume appeared in 1935.

While at the Treasury, Mr. Higgs was the first secretary of the Royal Economic Society and joint editor of the *Economic Journal* from 1892 until 1906. He had special knowledge of the thinkers of the eighteenth century; and his work on Cantillon and the Physiocrats was of a high order. His position at the Treasury enabled him to write with authority on questions of public finance. But, as his editing of Jevons's "Principles of Economics" (1905) and his repeated tenure of the Newmarch lectureship in statistics show, there was no aspect of economic thought with which he was not in contact.

Besides, Higgs had served as Inspector General of Finance in Egypt (1912–15) and had done other specialist work for the State. This made the range of his scholarship the more remarkable and explains the fact that, in spite of it, his learned output was rather fragmentary—the product of the hardly secured leisure of a very busy man. Some of the editorial work with which he was engaged after his retirement from public and academic activity was not of the kind to bring him much added reputation, and not all of it was equal to the work of his prime. In these last years he was, however, handicapped by failing health and almost complete deafness, which isolated him somewhat from colleagues and friends.

We regret to announce the following deaths:

Prof. W. F. Bork, emeritus professor of psychology in Indiana University, on May 22, aged sixty-six years.

Prof. A. Fowler, C.B.E., F.R.S., emeritus professor of astrophysics in the Imperial College of Science and Technology and in the University of London, and formerly Yarrow research professor of the Royal Society, on June 24, aged seventy-two.

Dr. Phyllis Tookey Kerridge, formerly lecturer in physiology, University College, London, on June 22.

Dr. Alvin S. Wheeler, emeritus professor of organic chemistry in the University of North Carolina, on May 12, aged seventy-three.

Prof. F. J. E. Woodbridge, emeritus Johnsonian professor of philosophy in Columbia University, on June 1, aged seventy-three.

NEWS AND VIEWS

Salvage and Utilization of Waste

A LEADING article in this issue of NATURE (p. 988) is devoted to a discussion of certain aspects of the salvage and utilization of waste. It is interesting to note that the sixth report issued by the Select Committee on National Expenditure consists of the conclusions reached by a Sub-Committee on Supply Services which has investigated the relation between the work of the Ministry of Supply and the Office of Works. These two departments are responsible for the provision of stores of various kinds, and, working independently as they do, they tend to compete with each other, thus causing unnecessary confusion.

The report recommends the appointment of a national controller of salvage, who shall direct the work of an inter-departmental committee which shall supervise the salvage work of all departments. A more intense publicity campaign for the salvage of waste products is recommended, and, in particular, it is suggested that the virtues of refuse dust as a fertilizer be made more widely known with the help of the Ministry of Agriculture and the National Union of Farmers. There is urgent need, too, for closer co-operation between the Salvage Department and the County War Agricultural Committees. This is particularly necessary in the important matter of the disposal of kitchen waste suitable for the feeding of pigs. There is no questioning the need for the appointment of a national controller of salvage with full power of co-ordination. The sooner the appointment is made, the sooner will the nation be in a position to use its so-called waste products effectively.

The Linnean Society during War-time

AT the anniversary meeting of the Linnean Society held on May 24, the retiring president, Dr. J. Ramsbottom, delivered his presidential address, the substance of which appears elsewhere in this issue (p. 993). Discussing the affairs of the Society, Dr. Ramsbottom said it was decided that at the beginning of the War it was not only in the best interests of the Society but also of biological science that the Society should remain in Burlington House. No matter what happens it is hoped that the present policy shall continue. The Linnean collections, the Smithian collections and certain other irreplaceable belongings have been removed. Thus all reasonable precautions with the Linnean collections have been taken; but what if they should meet with disaster ? During the time the collections have been away abundant evidence has been shown of the difficulties which arise when the Linnean Herbarium and the insect collection cannot be consulted. The Society has the negatives of photographs taken at various times of numerous specimens. Would it not be advisable to have photographs of the whole of the specimens taken under botanical or zoological supervision ? Prints could be sold to anyone and complete sets might be kept in one or two places : or it may be that reproductions could be published. It would be advisable also to photograph all the types in the Smithian Herbarium. There would be no point in publishing these, but records that can be preserved in safety would be available. The problem of manuscripts should also be considered. Would it not be wise to have microfilms or photostats of the Linnean correspondence and all important unpublished manuscripts in the Society's possession ? These again should be distributed.

Amateurs in Natural History

At the 150th anniversary meeting of the Society it was shown that it regards natural history societies as workers in the same field. Many prominent fellows of the Society are keenly interested in their local natural history societies. Dr. Ramsbottom thinks it would be well if the Society encouraged the idea that election to the Linnean Society of London should be the hall-mark of excellence in the study of natural history. If this were so the Society would continue to have that leaven of the amateur which is so necessary to the well-being of the Society. Amateurs were in the past the very backbone of British biology : it would be a sad blow to the democracy of science, even to science itself, if the Linnean Society were ever to be regarded as a domain reserved for the professional worker. "As a Society, then, our task during the War is to carry on as normally as possible, and to help others to do the same. In this connexion the Council has agreed to bring forward a motion, similar to one passed during the last War, that refugee biologists should be allowed certain privileges such as permission to attend meetings and to use the library".

H.M. Forces and Natural History

As individuals, fellows of the Society may have an opportunity of doing something, though not in a very spectacular way. There are many in H.M. Forces who might be helped over difficult periods if they became interested in natural history. Many of these men are seeing the common plants, birds and insects of the countryside for the first time, others in circumstances when their interest is easily aroused. Entertainment of the troops is usually of a certain type, excellent in its way, and nowadays the most popular of its kind. But some need more than mere amusement. It is not a matter of previous education but of temperament. The need may be met with music, or poetry, or other literature; for some it is in natural history. What can one say in answer to a letter asking whether the enclosed flower is a cowslip ? It may be to settle a bet—but it at least shows an interest and it is up to us to encourage any such interest, not with the intention of popularizing our special subjects, or for any other purpose whatsoever beyond helping these men to think of things other than evil ones. There is no need to organize such efforts. The more informal they are the better. Dr Ramsbottom suggests that any fellow who is prepared to help in this direction should get into touch with the Y.M.C.A. or similar organization at the nearest camp; or with the padres at the military hospitals. Here they will find a knowledge of individuals which is amazing, and an offer to talk to one or two men or to give a lecture on some aspect of biology which has a popular appeal will invariably be accepted.

Chair of Electrical Engineering, Birmingham

THE chair of electrical engineering in the University of Birmingham, vacated by the resignation of Prof. B. L. Goodlet, has been filled by the appointment of Dr. Cecil Dannatt. Dr. Dannatt has had many years experience with the Metropolitan-Vickers Electrical Co., Ltd., at Manchester, especially in the Research Department, where he has for some time been in charge of the Electrical and Magnetic Laboratory. His work has brought him into close contact with various branches of the industry and has given him opportunities of judging the needs and capabilities of young men in training for routine work and for research in electrical engineering. In the 1938–39 session, Dr. Dannatt was part-time lecturer in electrical engineering at Queen Mary College, University of London. Prof. Goodlet, who only took office in November last, resigned in order that he might make more effective use of his capacity in war-work elsewhere.

Books in War-time

IN NATURE of May 11, p. 719, we put forward the plea that books should not be subject to the proposed purchase tax. It has now been announced that on June 21 the Chancellor of the Exchequer received a deputation in this connexion composed of representatives of the church, literature, science, and education. The deputation consisted of theArchbishop of Canterbury (who introduced the deputation), Sir Arthur Eddington, Lord Hambleden, Mr. A. P. Herbert, M.P., Prof. A. V. Hill, Dr. Albert Mansbridge, Mr. J. B. Priestley, Sir Charles Grant Robertson, and Prof. R. H. Tawney. The Bishop of Chichester and Sir Will Spens were unavoidably prevented from attending. The deputation was accompanied by Mr. Geoffrey Faber and Mr. G. Wren Howard, president and vice-president of the Publishers' Association, and Mr. Stanley Unwin, chairman of the Books and Periodicals Committee of the British Council.

Pest Control Chemicals

AT a recent meeting of interested firms, the Pest Control Chemicals Export Group was formally inaugurated, with headquarters at 166 Piccadilly, London, W.1. The Group has now received the recognition of the Export Council of the Board of Trade. The broad object of the Group is to promote the export trade in such chemicals. Any British persons, firms or bodies corporate actively engaged in the manufacture and export of pest control chemical products, such as (a) disinfectants, (b) sheep and cattle dips, (c) agricultural insecticides and fungicides and (d) animal medicines and allied products are eligible for membership of the Group. The main Group comprises four autonomous sub-groups to deal with the problems arising from each of these sections of the industry. Thirty-six firms have already signified their intention of joining the Group. The first problems of the Group will be in connexion with materials in short supply.

Evulsion of Front Teeth in East Africa

IN reference to recent comment in NATURE (April 20, p. 631) on Dr. Aleš Hrdlička's study of the practice of removing the front teeth found among primitive peoples, Dr. Frank Marsh, c/o Anglo-Iranian Oil Co., Ltd., Pathological Laboratory, Abadan, Iran, suggests an alternative to the ritual origin of the custom, based upon his experience in British East Africa. There, he points out, the practice of removing the incisors is almost entirely confined to the Masai and related tribes. These tribes are warrior castes who under their natural (pre-controlled) condition lived by and for fighting; and in the course of this pursuit they expected to receive wounds, especially from arrows carrying poison derived from putrescent flesh. The juices of putrefaction contain large numbers of the spores of *Clostridium tetani*, causing lockjaw. The victim is then fed on milk and other liquids introduced through the toothless gap. Some recover—a result rare among civilized peoples. Dr. Marsh suggests that this may be a definite practical reason for the ritual removal of the teeth.

While it is unquestionable that practical experience of the kind to which Dr. Marsh refers would tend to perpetuate the practice in a given group of people, its influence probably is secondary. Various reasons are given by peoples who follow the practice; for example, it may be related to the escape of the soul from the body at death; while it is too widely distributed in time and space—it occurs among the mesolithic peoples of Palestine and North Africa—for it to be likely that a single practical purpose is implicated in all the varying conditions alike.

The Populations of Southern Algeria

DR. MAURICE GRONIER devotes his inaugural thesis (*Thèse de Paris*, No. 163; 1940) to the anthropological features and peculiarities of disease of the inhabitants of southern Algeria. The Arab population is characterized by a fairly high average stature, distinct dolichocephaly and leptorhinia, while the Mzabite population is distinguished by a higher stature, a relatively long trunk, a tendency to mesocephaly and a higher nasal index. The dentition of these populations is remarkably good, there being an exceedingly low percentage of caries. In addition to widespread malaria, parasitic invasion of the skin and alimentary canal and especially trachoma, the points in which the natives of southern Algeria show a striking contrast with Europeans are as follows:

the absence of the nervous complications of syphilis in spite of the prevalence of that disease, the low incidence of diseases of the liver, the rarity of appendicitis, the frequency of pain in the region of the solar plexus, the prevalence of the osteo-articular and glandular forms of tuberculosis and the frequency of cataract in elderly persons.

Euthanasia

IN the April issue of the *Quarterly Review*, Sir Arthur Hurst discusses the question of euthanasia from a practical point of view without any sentimental considerations. Those in favour of the practice, he points out, maintain that euthanasia should only be carried out on persons who are affected with an incurable and painful disease, which cannot be controlled by any form of treatment. On the other hand, the cases in which euthanasia appears most desirable do not come within the scope of the Euthanasia Act, which requires the expressed desire of the patient that his life should be ended. Such cases are those of new-born babies with severe deformities or conditions preventing normal mental development, or that of the intelligent man who becomes paralysed and is unable to communicate his wishes by speech or writing.

Sir Arthur condemns the unjustifiable confidence displayed by the advocates of euthanasia in the ability of two independent medical advisers, however experienced they may be, to decide whether a disease is incurable, and quotes several examples of patients condemned to death by eminent physicians or surgeons making an unexpected and complete recovery. In undoubted cases of incurable and painful disease, in which no relief can be obtained except by morphia, Sir Arthur recommends that the patient should be kept permanently free from pain by gradually increasing the dose and giving the injections as often as is necessary. Moreover, pain can be controlled not only by drugs but also by surgical operation, which is particularly indicated when the painful disease is not likely to be rapidly fatal and the administration of morphia is therefore undesirable.

Photo-cell Applications in the Foodstuffs Industries

IN commerce the difference between one quality of rice and another consists mainly in the proportion of discoloured grains present. Since hand-sorting has never been commercially practicable, the mechanical and electrical method of sifting out the discoloured grains by a machine, described in a paper by A. Seymour in the *Electrical Times* of June 6, may have far-reaching effects. The machine utilizes the properties of a photo-cell. By an ingenious mechanical method, the grains emerge from the feeder in a single line at a speed of 5 ft. per sec. and pass under the electric 'eye'. The perfect grains shoot straight forward into a tube leading downwards to a sack. Discoloured grains cause an electrical impulse through the photo-electric cell; this brings into action a jet of compressed air, which sends them into another receptacle.

Examination of granulated sugars is more elaborate, as it includes a classification of the finished sugars for general appearance and an evaluation of the colour and turbidity of the sugar solutions. Experiments with photo-electric apparatus have shown that good correlation exists between the appearance of a sample of granulated sugar and its reflectance relative to magnesium oxide. A specially designed optical system in the photo-electric apparatus permits measurements of the transmittancy of sugar solutions as well as of the reflectance of the sugar in granulated form. Numbers obtained from these data enable the expert to compare the relative merits of the samples.

The Edinburgh Botanic Garden

A PAPER by John M. Cowan (*J. Roy. Hort. Soc.*, 65, Pt. 3; March 1940) describes the various botanical personalities who have contributed thought and organization to the development of the Royal Botanic Garden, Edinburgh. This is one of the oldest 'physic' gardens in Britain, and was established in 1670 by Robert Sibbald, with help from his friends Andrew Balfour and Patrick Murray. The first 'intendant' was James Sutherland, whose subsequent appointment as the first professor of botany at the University of Edinburgh ensured that close co-operation between academic plant science and practical horticulture which has been so marked a feature of the institution throughout its history. The Prestons, Charles Alston and John Hope succeeded Sutherland, each adding patiently a solid quota of work. Rutherford, discoverer of nitrogen, was also in charge of the garden, and more recently, J. Hutton Balfour and Sir Isaac Bayley Balfour have enhanced the reputation of the garden as an academic centre. It now possesses modern laboratories, and provides a stimulating part of the curriculum for students in medicine, arts, pure science, forestry and agriculture.

Road Obstruction Lanterns

THE General Electric Co., Ltd., has developed a road obstruction lantern which complies strictly with the Lighting (Restrictions) Order, 1940. The use of these electric lanterns for fixing to street bollards or other supports has many advantages. Not only does it mean a saving ranging from 2*d*. to 6*d*. per lamp per day, but it also saves in oil and man-power. According to *Roads and Road Construction* of June 1, in one London borough alone the saving effected in this way amounts to nearly £5,000 a year. The G.E.C. lantern is constructed of lead-coated sheet steel and has three sides, stencilled with the approved St. Andrew's Cross sign and backed with white opal glass. Inside are a detachable baffle and a B.C. lampholder for use with a 15-watt pearl Osram lamp. This provides the correct amount of light (0·5 candle per square foot) on the crosses. The lamp is easily accessible for wiring and maintenance. The lantern is supplied finished with either black or white outside. A two-lamp unit is preferred by some authorities because of the advantages of ensuring that there is a light on the island even if one lamp fails. The cost of the G.E.C. two-lamp lantern is little greater than that of the standard unit.

arthquakes during May 1940

URING May 1940, eighteen earthquakes were tered at the Swiss Seismological Observatories asle, Chur, Neuchâtel and Zurich. The observers rich have estimated the epicentres of the larger s as follows : May 1, in the province of Parma aly ; May 4, in the Pacific Ocean east of the chatka Peninsula near lat. 50° N., long. 170° E. ; 7, in Anatolia near lat. 42° N., long. 34° E. ; 19, one again near the Kamchatka Peninsula t lat. 49° N., long. 158° E., and one possibly in Indian Ocean ; May 24, one near Lima in Peru, one in Central Germany.

e United States Coast and Geodetic Survey, in eration with Science Service and the Jesuit nological Association, has made a preliminary mination of the epicentres of the earthquakes ay 11 and 17. On twelve seismometric reports picentre of the shock of May 11 was calculated near lat. 53·2° N., long. 172·0° E., which is near sland of Attu at the extreme western end of the tian Islands. On the basis of instrumental rts from Fordham, Ottawa, Weston, Pittsburg, Louis, San Juan, and Huancayo, the epicentre e earthquake of May 17 turned out to be near 7·9° N., long. 81·8° W., which is just in the ic Ocean off the coast of Panama to the south- of Pueblo Nuevo. Most of these shocks were recorded at Kew.

Night Sky in July

N July 1, the duration of night (sunset to sunrise) ne latitude of London is 7·5 hours ; astronomical light (the sun not greater than 18° below the izon) lasts all night until July 21. The moon is on July 5 and full on July 19. The moon is in unction with Mars on July 6, with Jupiter and rn on July 28 and with Venus on July 31. From western parts of North America, Venus will be to be occulted by the moon at this conjunction laylight. There is no bright planet conspicuous in the evening skies, since Mars—the remaining mber of the notable group of bright planets seen the evenings of the early part of this year—is ting too close to the sun for observation. At the ginning of the month, Jupiter and Saturn rise thin a quarter of an hour of each other not long r midnight (U.T.). Venus is the bright morning seen about one hour before sunrise in the middle July and 2½ hours before sunrise at the end of the nth. The planet is increasing in brightness towards maximum on August 2. Close groupings of piter's four inner satellites (to be seen with oculars) occur about 2h. on July 2, 12, 20, and 21. e ring system of Saturn is well open, the minor s of the outer ellipse of the outer ring being greater n 13″. The delta Aquarid meteors reach a ximum frequency about July 28.

ouncements

T its meeting on June 21, the Council of the er Institute appointed Prof. C. R. Harington one of its representatives on the Governing Body of the Institute in succession to the late Sir Arthur Harden.

THE Royal Meteorological Society has awarded its Howard Prize (an aneroid barometer, given annually for the best essay on a selected meteorological subject) to Cadet S. R. Pryor of the S.A.T.S. *General Botha*. The subject of the essay was "The Relation of Wind to Ocean Currents".

AT the annual general meeting of the Royal Geographical Society, it was announced that the King, having approved the awards of the Founder's and Patron's Medal, had signified through the Keepers of the Privy Purse that the gold medals could not be struck until after the War. The complete list of the Society's awards was given in NATURE of April 27, p. 665.

THE annual general meeting of the British Social Hygiene Council will be held at British Medical Association House, Tavistock Square, W.C.1, at 4.30 p.m. on July 8. The president, Sir Walter Langdon-Brown, will deliver an address on the activities of the British Social Hygiene Council since the outbreak of war. Tickets of admission may be obtained on application to the Secretary, B.S.H.C., Tavistock House South, Tavistock Square, W.C.1.

DR. E. H. CLUVER, secretary for public health and chief health officer for the Union of South Africa, has been appointed director of the South African Institute for Medical Research in succession to the late Sir Spencer Lister.

THE Plunket Society or Royal Society of New Zealand for the Health of Women and Children is proposing to erect a monument to its founder, Sir Truby King, whose system of infant feeding largely contributed to making the infantile mortality in New Zealand the lowest in the world.

A GIFT of a thousand dollars has been made to the International Association for the Prophylaxis of Blindness to promote research in ophthalmology. The subject chosen for a prize, which will be awarded on the occasion of the tenth International Congress of Ophthalmology, is simple non-inflammatory glaucoma. The address of the Association is 66 Boulevard Saint-Germain, Paris.

A PROGRAMME of some thirty papers on the applications of spectroscopy to problems of biology, chemistry, geology, metallurgy, medicine, physics, and various industries, has been arranged for the eighth summer conference on spectroscopy and its applications, to be held in the George Eastman Laboratories of the Massachusetts Institute of Technology during July 15–17. Further information can be obtained from Prof. George R. Harrison, Department of Physics, Massachusetts Institute of Technology, Cambridge, Massachusetts.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. They cannot undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.*

IN THE PRESENT CIRCUMSTANCES, PROOFS OF "LETTERS" WILL NOT BE SUBMITTED TO CORRESPONDENTS OUTSIDE GREAT BRITAIN.

NOTES ON POINTS IN SOME OF THIS WEEK'S LETTERS APPEAR ON P. 1024.

First Use of Current-Bedding to Determine Orientation of Strata

DR. ROBERT M. SHACKLETON[1] has recently completed a revision of the structures of the Silurian and Devonian rocks of the Dingle Peninsula and Blasket Islands in south-west Eire. In this he has used the positions of truncated tops and asymptotic bases of current-deposited laminæ in order to determine the correct order of succession, and has been able to demonstrate the probable equivalence of Anascaul Beds with Ferriter's Cove and Croaghmartin Beds (Silurian) and of Smerwick Beds with Dingle Beds (Downtonian). Axes of folding that trend from east-north-east to west-south-west have been plotted, and inverted beds are conclusively recognized on the north and south margins of the Peninsula and at Clogher Head. The final proof that the axis of an overfolded syncline runs through Ventry Harbour, Fahan Point, and between the Great Blasket and the two smaller islands of Inishnabro and Inishvickillane, vindicates the work of G. V. Du Noyer prior to 1859 in first tracing the inversion south of this important line and describing it despite opposition by J. Beete Jukes[2], director of the Irish Geological Survey.

It is also of interest from the historical point of view to recall that it was from the Dingle Beds, at Slea Head, facing the Great Blasket, so early as 1864, that figures of false-bedding, used to decide which way up strata were lying, were published by John Kelly[3]. He concluded from the diagrams reproduced in the accompanying figure that at Slea Head the beds had their original tops orientated upwards, and showed that successive sets of laminæ were deposited by currents flowing at different times from approximately opposite directions. Kelly's conclusions have now been fully supported, so that it may be opportune to quote part of his pioneer description :

"In the laminæ of that part of the bed marked *a*, the thick end of every minor layer is uppermost, the fine point at the bottom and the curve downwards. In this case the view at Slea Head is taken so that the observer is looking towards the north, and it is evident that the current which brought the grains of sand to form the groups of laminæ *a*, *a*, *a*, came from the west; the current that brought and deposited the group *b* came from the east. . . .

". . . another sketch taken on the south coast of Slea Head, at Reenrooig . . . is of similar character . . . but in this case nearly all the sediment was brought from the west, only one group appearing to have come from the east. . . .

"This fact of the thick end of the laminæ of deposition being up and up stream, and the point downwards and down stream . . . is important, inasmuch as from it we may know . . . what side of a bed was uppermost when it was deposited, and thus

in the Silurian and Devonian beds of the sout
Ireland, it may be known where steep dips or c
plex contortions present themselves, whether
original upper side of a bed is still uppermost,
whether a group of beds has been overthrown
turned upside down, as is sometimes the case.

"These facts were noticed by Mr. Patrick G
who made numerous drawings of this kind of la
tion about Slea Head for Sir Richard Griffith."

John Kelly goes on to describe the relation bet
ripple-marks and false-bedding. His account
matured one, so that probably the results date f
some years earlier than the time of publicatio
1864. The author seems to be the same perso
the J. Kelly engaged as an assistant geologist al
with Du Noyer in the survey of Dingle. Ther
therefore, little doubt that these remarkably mo
views were known in Ireland when the Su
Memoir of 1863 appeared. In them we may have
clue to Du Noyer's positiveness about the inve
of certain beds, now justified by Dr. Shackle
But there is nothing of this evidence in the me

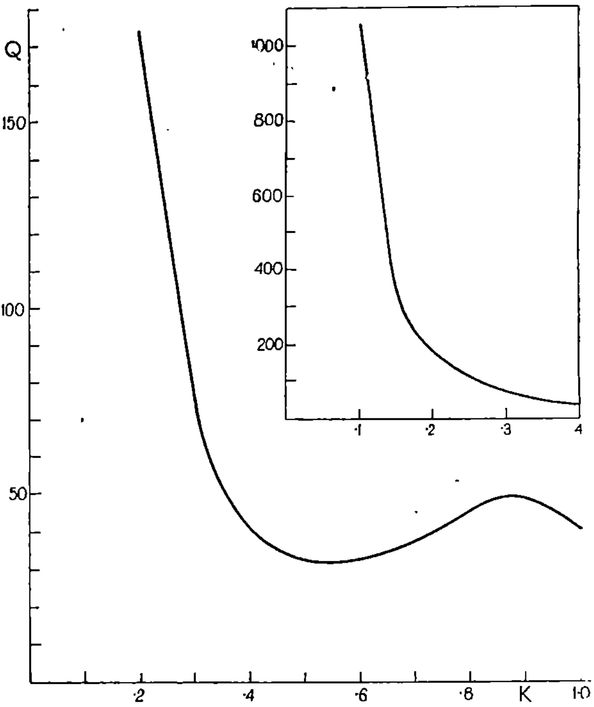
ross-section of Atomic Oxygen for lastic Collision with Electrons, and Region *F* Absorption

is now generally agreed that the higher regions he atmosphere—beyond 150 km.—consist pre- antly of atomic oxygen. The absorption of waves in Region *F* of the ionosphere which ove this level is thus caused by collision of ons with neutral oxygen atoms. If one wants timate theoretically the frequency of such on, a knowledge of the cross-section for elastic ion of atomic oxygen becomes necessary; we therefore thought it desirable to calculate it uantum mechanics methods for various electron gies up to 13 volts. The method employed for erical solution is that developed by Hartree[1] for determination of self-consistent fields. The s obtained are shown in the accompanying curves. ollisional cross-section is seen to increase rapidly anner not observed for the cases of N_2 and O_2.[2] act that atomic oxygen exhibits the Ramsauer , as seen from the figure, is of importance in nterpretation of absorption processes occurring egion *F*.

e curve may be utilized for calculating the sional frequency in Region *F*. If the temperature he region be taken as 1,000° K., after Martyn Pulley[3], and density of oxygen as 4×10^9 atoms c., after Mitra and Rakshit[4], then the collisional ency calculated by using the appropriate cross- on obtained from the curve is found to be 10^3/sec. This agrees with the value 2×10^3/ which is the mean of the values obtained by s workers from radio measurements[5]. It l be pointed out that even a large change in the ed value of temperature of the electrons does not produce any marked change in the calculated value of the collisional frequency. This is because an increase in collisional frequency due to the increased average velocity is roughly balanced (as may be seen from the curves) by the decreased cross-section. It may be noted that the collisional frequency calculated by taking the gas kinetic cross-sections yields a value of only 70 per sec., which shows that for such slow collisions as occur in the ionosphere, one must use the quantum mechanics calculated cross-section and not the gas kinetic cross-section.



Q, CROSS-SECTION OF O I FOR ELASTIC COLLISION WITH ELECTRONS.

K, $\sqrt{\frac{\text{ELECTRON VOLT}}{13\cdot53}}$

It is, however, interesting to note that for Region *E* the collisional frequency calculated by taking the gas kinetic cross-sections of N_2 and O_2 (predominant gases in Region *E*) agrees with the result obtained by radio method. This, as has been pointed out[6], is due to the fact that the values of gas kinetic cross-sections of N_2 and O_2 accidentally agree with those computed by quantum mechanics for the range of electron energy considered.

A fuller and more detailed account will shortly be published in the *Indian Journal of Physics*.

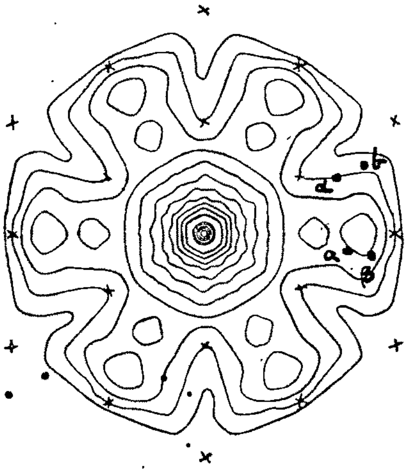
Patterson Projection of the Skeletons of the Structure proposed for the Insulin Molecule

IN a communication in NATURE[1], Riley and Fankuchen claim to have disproved the structure C_2 predicted for the insulin molecule[2] by means of a Patterson projection of the cyclol skeletons. Great weight has been given to this result[3,4]. My opinion was[5], and is, that the claim to have produced from the $(C{-}C{-}N)_{288}$ skeletons arranged at a tilt of 6°, a Patterson projection which has high intensities where they should be low (at *A*, points midway between pairs of adjacent molecules) and low intensities where they should be high (at *B*, points midway between trios of adjacent molecules) proves little in view of the fact that less than 27 per cent of the crystal has been considered[6].

Recently I have examined closely the bases of the claims advanced in this article. They rest upon (1) the basal projection of the C_2 skeleton shown in their Fig. 1; (2) the corresponding Patterson map in their Fig. 2; and (3) the Patterson map obtained by superposing the individual maps in the crystal lattice shown in their Fig. 3. I find that (1) is incorrect. It contains 850 atoms whereas it should contain 3 × 288 = 864 atoms. While the absence of two of the atoms appears to be due to misprints, the other 12 missing atoms seem to have been overlooked. Further, since it is claimed that "those parts of the cyclol molecule which have definitely and precisely been worked out by Wrinch" have been taken into account, it is necessary to point out that all the 288 C_β atoms and the skeletal oxygens have been omitted from consideration. (2) The tilt of the molecules is not defined by the crystallographical data. It is, however, obvious from Riley and Fankuchen's Fig. 2 that a small tilt (say, 0–10°) gives low *A* intensities and high *B* intensities, whereas a large tilt (say, 30–40°) gives low *B* intensities and high *A* intensities. The former is the situation found by Crowfoot[7] in her projection calculated from X-ray intensities, and a small tilt of about 6° (see NATURE, **142**, 582, Fig. 2) has been suggested by Wrinch[8] and by Wrinch and Langmuir[9] on the basis of the strong $(8, \bar{7}, \bar{1}, 0)$ reflection and for a number of other reasons.

To make the situation as precise as the rough sketch map allows, there is reproduced herewith Riley and Fankuchen's Fig. 2, to which have been added the points *a* and *b* and the points α and which represent, when the tilt is 36° and 6°, one h and one third, respectively, of the intensities at and *B*. The sketch map is unsupported by numerical values calculated, but numbering contours 0, 1, 2 . . . inwards, it appears t (roughly) $a = 2{\cdot}75$, $b = 0{\cdot}75$, $\alpha = 1$ and β giving $A = 5{\cdot}5$ and $B = 1{\cdot}5$ for a tilt of 36°, $A = 2$, $B = 9$ for a tilt of 6°. Although it is stat by Riley and Fankuchen that a tilt of 6° has b chosen, an examination of their Fig. 3 shows th tilt of 36° has been chosen, giving of course h intensities at *A* and low intensities at *B*.



On the basis of the facts here pointed out, all claims of these authors fall to the ground and th laborious calculations (assuming that the omitt atoms do not seriously affect their Patterson ma appear to show that the contrary of what they say true. With a tilt of 6°, they appear to have prov that the Patterson map of the C_2 skeletons gives l intensities at *A* and high intensities at *B*, in accordan with the findings of Crowfoot.

Depth of Focus of Microscope Obje

IT is usually assumed that the depth of fo of a well-corrected microscope objective is giv one or other of the following formulæ:

$$(A)\quad t = \frac{\lambda\sqrt{N^2 - (\mathrm{N.A.})^2}}{(\mathrm{N.A.})^2}$$

(Hardy and Perrin: "Princi Optics", p. 511.)

or

$$(B)\quad = \frac{\lambda}{4N\sin^2\left(\frac{1}{2}\sin^{-1}\frac{\mathrm{N.A.}}{N}\right)}$$

(Conrady: "Dictionary of A Physics", vol. 4, p. 222).

where N is the refractive index of the medium thro which the light travels, λ the wave-length of the li used, and N.A. the numerical aperture of the objecti

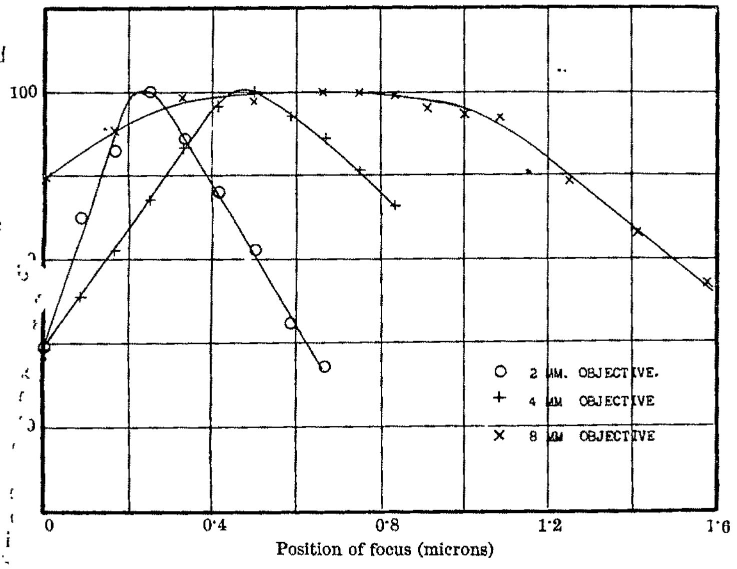
These formulæ lead to the following depths focus for the objectives given, in light of wave-len 5000A.

Objective	N.A.	Depth of focus (micro Formula *A*.	Formul
2 mm. oil immersion ..	1·30	0·22	0·3
4 mm. dry	0·95	0·18	0·3
8 mm. dry	0·65	0·90	1·0

Graton and Dane[1] have, however, pointed out t the depth of focus appears to be much less tha expected theoretically, and I have recently m some investigations on the subject.

Very fine dust particles, mounted dry and ran down to a size known to be smaller than 1/10 mic have been photographed in blue-green light methods described elsewhere[2] using Beck apoc matic objectives of the above types. By cour the numbers of particles photographed on p taken at foci varying by about 1/12 micron, estimate of the depth of focus of the objective obtained. The results, after correction for curvure of field present in the photographs, are plotted the accompanying graph. It must be noted that different objectives photograph down to different s of particles, and this factor makes it impossible compare the curves with each other.

t will be seen from the graph that with both the mm. and 4 mm. objectives, when the focus is out either side of the best focus by more than about . micron, the number of particles photographed significantly less than the maximum number otographed. The finest particles photographed the best focus have a thickness which is not known actly but which is believed to be of the order of 06 and 0·09 microns for the two objectives respect- ely; this amount must be subtracted from the parent depth of focus. It seems certain, therefore, at both these objectives have a depth of focus of ss than 0·15 micron, and the depth of focus may tually be very much less. This could be deter- ined more accurately by using a still finer adjust- nt, but, at present, time does not permit of this estigation.



With the 8-mm. objective a certain portion of the rve is flat, but the flatness does not extend over a nge of more than 0·70 microns; as the thickness of rticle photographed with this objective is prob- ly of the order of 0·14 microns, it seems that the pth of focus of this objective is certainly less than 55 microns and may be about 0·40 microns.

Naturally these depths of focus are increased by e adaptability of the eye when the objective is used sually.

It is obvious from these results that the present rmulæ for the depths of focus of microscope jectives give values which are considerably higher n those found experimentally.

Diffraction Maxima in X-Ray Photographs

IN a recent communication[1] C. V. Raman and P. Nilakantan report the presence in Laue photographs of weak intensity maxima which cannot be interpreted as Laue spots. They suggest that the new maxima are due to lattice vibrations which cause stratifications of density with the same spacing as the lattice planes, but with an orientation variable between wide limits.

The effect observed by these investigators is not new. Such weak spots are commonly found in Laue photographs taken with an X-ray beam containing characteristic as well as continuous radiation. If the incident beam does not contain appreciable amounts of characteristic X-rays, radial streaks rather than spots appear in the Laue photographs. Earlier investigators have directed attention to these streaks or spots[2], and G. D. Preston (l.c.) demonstrated that the intensity of the spots increased with the temperature. Moreover, I presented a detailed theory of the effect before the American Physical Society at its meeting on December 1, 1939. An abstract of this paper was published in November last in the *Bulletin of the American Physical Society* and afterwards in the *Physical Review*[3].

According to this theory, the lattice vibrations cause diffuse scattering of X-rays showing a rapid intensity variation with the scattering direction. The intensity maxima are to be found in the directions u_m given by the equation $(1 + \lambda\tau)u_m = u_0 + \lambda B_H$, where u_0 is the direction of incidence, λ the wave-length of the X-rays, B_H a reciprocal lattice vector and τ the wave vector associated with a mode of vibration of the lattice.

The assumption of Raman and Nilakantan that the new maxima are due to lattice vibrations is thus confirmed. It should be pointed out that the positions of the maxima are not given by the Bragg law as Raman and Nilakantan seem to suggest. In the Laue photograph of diamond reproduced in their communication, the auxiliary maxima appear at a scattering angle of 43° 0′ ± 25′, as compared to 43° 16′ deduced from the equation given above and 43° 58′ from the Bragg equation.

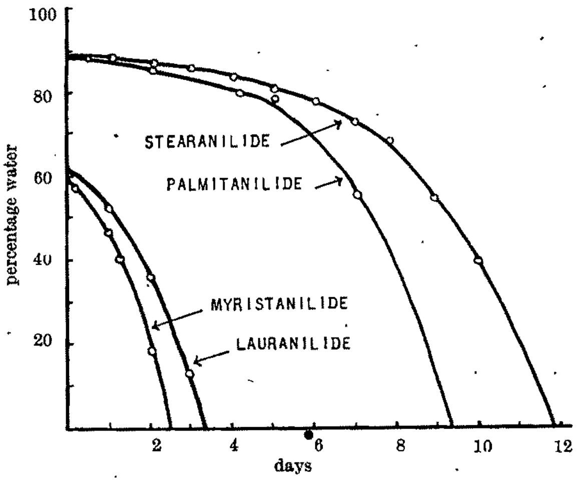
Hydration of Anilides of Normal Fatty Acids

I HAVE previously described the formation of hydrated stearanilide[1]. An investigation of some of the factors influencing the binding of water by substituted amides of the normal fatty acids is now in progress. Since experiments of an exploratory character had shown that both the amount of water taken up and the tenacity with which it is held vary with the mode of hydration, a standard procedure for the production and examination of the hydrated compounds has been adopted.

5 gm. of the pure anhydrous amide is dissolved in 50 c.c. hot absolute alcohol and the solution rapidly stirred into 1 litre of cold distilled water. The hydrated amide, precipitated as a bulky white mass, is allowed to float in the water for 20 hours. It is then filtered off at the pump, drained by suction, spread out on a porous plate and dried over fused calcium chloride for 24 hours at atmospheric pressure. Samples (5–10 gm. each) of the material are examined by heating to constant weight in an oven (the oven temperature being about 10° below the melting point of the anhydrous amide) and by drying in open Petri dishes over fused calcium chloride both at ordinary pressure and *in vacuo*. In this way the total water content of the material is determined and an assessment of the tenacity with which it is bound can be attempted.



As a start, the influence of chain-length on water-binding capacity has been studied by examining the hydrated anilides of stearic, palmitic, myristic and lauric acids. In the accompanying figure are shown the percentages of water in samples of the hydrated compounds at intervals during drying over fused calcium chloride at ordinary pressure. It would seem that the ability to 'bind' water is possessed only by stearanilide and palmitanilide, for although both myristanilide and lauranilide take up considerable amounts of water, neither is able to hold it firmly enough to resist ordinary desiccation.

At this stage it seems not unreasonable to suggest that the water of hydration is held in the interstices of a micellar structure. Points in support of this view may be summarized thus : (1) the large amount of water bound, (2) both the anhydrous and hydrated anilides are hydrophobic, (3) heating the hydrated compounds to within about 5° of the melting point of the anhydrous amide results in the setting free, in liquid form, of all the bound water[1].

Carrageen Mucilage

FOR some time we have been studying the mucilaginous polysaccharides of carrageen moss, and now seems desirable, in view of the recent letter b Dillon and O'Colla[1], to communicate some of o results.

Preliminary experiments on the composition of t polysaccharide (hot extract) obtained by extractio with hot water as described by Haas[2] has confirme his view that this was essentially the calcium salt a carbohydrate ethereal sulphate, analysis of t ash (19 per cent) giving Ca, 5·6 per cent, SO_4, 12·5 p cent calculated on the original hot extract, tot SO_4, 24 per cent.

Acetylation with pyridine and acetic anhydrid under various conditions and for long periods wa completely unsuccessful both on the hot extract an other carrageen extracts. It is significant that th acetolysis method of Dillon and O'Colla[1] caused extensive degradation, not only removing th ethereal sulphate residues but also the non-galactosic components.

Hydrolysis yielded a mixture of sugars containin galactose (*c.* 50 per cent) and this appears to be th main building unit of the molecule although it accompanied by other sugars. According to th results of Dillon and O'Colla[1], the galactose seems t be contained in the most resistant portions of th molecule since by their acetolysis method galactan appear to be produced. Although the rest of th hydrolysis mixture yields glucosazone, contains small amount of pentose, and gives some colou reactions for a ketose, its composition is as y undecided.

Direct methylation of the hot extract proved d cult and the methoxyl content could not be incr beyond *c.* 15 per cent, the ethereal sulphate res however, being retained. Hydrolysis followe acetylation and distillation in a high vacuum yie a dimethyl hexose triacetate (*c.* 40 per cent) an monomethyl hexose tetra-acetate (*c.* 20 per ce both of which on methylation and suitable treatm gave tetramethyl galactopyranose anilide in go yield, and deacetylation followed by osazone for tion yielded 6-methyl *d*-galactosazone and *d*-galacto zone respectively. If one assumes a pyranose ri to be present, although this is not necessarily t case, and takes into consideration that the pol saccharide is non-reducing and that therefore C_1 i involved in the linkage between adjacent units, i appears that in some units at any rate the second 'polysaccharide link' is on either C_3 or C_4 with th ethereal sulphate residue in the vacant position. I is clear, both from the methoxyl content of the methylated polysaccharide and from the isolation o 2-methyl galactose derivatives, that unless on hydroxyl group—probably on C_6—is occupied i some units by a residue resistant to methylatio there must be some shielding effect, possibly due t the sulphate residue, and this may also explain th difficulties of acetylation. The presence of tw ethereal sulphate groups on one anhydro-galacto residue must be excluded, for this would require much higher sulphate content than is observe Finally, since the hot extract is essentially a calciu salt, adjoining chains of carbohydrate residues mu be joined together by the divalent element, and t may have some bearing on the highly viscous so tions which are obtained and the difficulties acetylation and methylation.

Further work is in progress on the non-galactosic portion and also on the polysaccharides extracted by cold water.

Native State of Proteins in Egg-White

There are two opposing conceptions of the native state of proteins in biological fluids. One holds that the native particle is a complex of the various species of proteins present and is altered in the process of isolation. The other supports the independent existence of these species in a state of homogeneous dispersion. Difficulties of separation and inconstancy in amino-acid analyses support the former, and these were encountered[1] in efforts to separate and characterize the proteins in hen's egg-white. Block[2] has suggested the existence of an 'orosin' in egg-white on the basis of the ratio of arginine, histidine and lysine. The evidence from physical methods with blood serum supports the second hypothesis, but these have not been applied to egg-white except for a brief note by Svedberg[3] relative to irregularities in the sedimentation constant of native and 'purified' ovalbumin.

Egg-white has been examined in the ultra-centrifuge at 60,000 (± 300) r.p.m. in a field strength of 270,000 times gravity using the 'diagonal schlieren' method of Philpot[4] in the optical system and a high-pressure mercury vapour lamp. The temperature of the rotor was 25–27° and the period of spinning up to five hours. Native egg-white and that diluted with 1 per cent sodium chloride from one to three times exhibited a single sedimenting boundary. The concentration of total protein varied from 9·8 to 2·6 per cent, measured by the Zeiss dipping refractometer and light of wave-length 546 mμ.

The differentiation of the native proteins in the white was attempted on the basis of ionic mobilities by the method of Tiselius[5]. The migration of the boundaries was followed optically by the 'schlieren' method using a sodium vapour lamp. The native or diluted egg-white was dialysed previously at 2° against a phosphate buffer mixture of pH 7·2 and 0·1 μ ionic strength until equilibrium was attained and chloride removed. Egg-white diluted three times, twice and once with buffer solution and exhibiting concentrations of total protein of 1·95, 2·75 and 4·00 per cent, separated into five and sometimes six boundaries. The electrophoresis was continued for three hours at a potential gradient of 120 v. and 10 mA. and a temperature of 1° C. In the most concentrated preparation three of the bands were heavy and three relatively light. A fresh preparation, with a protein concentration of 5·57 per cent, made with a phosphate buffer of pH 8·0 and 0·1 μ ionic strength gave a similar result in five hours of migration. The concentration of the original egg-white was 9·77 per cent. It has not been possible to study the migration of the native white without some degree of dilution by phosphate buffer. However, this is in remarkable agreement with the conclusion of five distinct protein components reached by Hektoen and Cole[6] on the basis of immunological reactions. The chemical methods of separation would, therefore, seem to have a degree of justification.

The chemical individuality of the products thus separated was tested. Using methods previously described[1], ovomucin and ovomucoid were very carefully fractionated and obtained in solution after dialysis against phosphate buffer of pH 7·2. Such solutions were never homogeneous. The best preparation of ovomucin showed a single boundary by electrophoresis but two by centrifugation in a concentration of 1·33 per cent. A specially purified preparation of ovomucoid showed three migrating boundaries in the Tiselius apparatus at 2·7 per cent concentration but only one sedimenting boundary in the centrifuge. The results thus appear to justify the further conclusion that our chemical methods are not yet adequate for the separation of the five or six species of protein in native egg-white.

The present note is published at this time because no further work appears possible in the immediate future. I wish to acknowledge the kind hospitality of Sir John Ledingham and Dr. A. S. McFarlane at the Lister Institute during the summer months of 1938, and the sympathetic assistance of Mr. R. A. Kekwick.

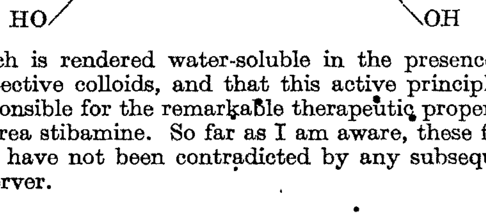
Chemistry of Urea Stibamine

In his article on the "Antimony Treatment of Kala-azar"[1], Sir Leonard Rogers referred to the findings of an early worker on the constitution of urea stibamine; reference was not made to later work on this subject, notably that of Gray *et al.*[2].

To some extent the controversy about the constitution of urea stibamine is comparable to that about atoxyl when it was discovered by Ehrlich. Gray *et al.* have noted that the most interesting of the more important derivatives of p-amino-phenyl stibinic acid is a material prepared by Brahmachari (1922) under the name 'urea stibamine' by heating P-amino-phenyl stibinic acid with urea solution. They have shown that the 'essential active principle' in urea stibamine is S-diphenyl-carbamide-4 : 4 distibinic acid



$$O = \overset{HO}{\underset{HO}{Sb}}.C_6H_4.NH.CO.NH.C_6H_4\overset{OH}{\underset{OH}{Sb}} = O\,,$$

which is rendered water-soluble in the presence of protective colloids, and that this active principle is responsible for the remarkable therapeutic properties of urea stibamine. So far as I am aware, these findings have not been contradicted by any subsequent observer.

I would also point out that Gray *et al.* found fairly constant results from analysis of urea stibamine (Brahmachari), as shown in the accompanying table (the discrepancy in the antimony content of samples examined by them being due to varying amounts of the protective colloids present):

Carbon	Hydrogen	Nitrogen	Antimony
—	—	6·75	44·19
—	—	6·77	44·49
20·2	3·0	—	—
20·9	2·9	—	—
20·5	2·8	—	—
20·9	3·0	—	46·4
21·53	2·67	—	—
21·16	2·8	—	46·8
20·17	2·91	6·47	48·6

As already noted in NATURE[3], the divergent results obtained by different investigators were due to the fact that various manufacturers put on the market so-called urea stibamine which did not conform to my specification. This no doubt led to the conclusion of early workers that the so-called urea stibamine varied widely in its antimony content and was uncertain in its composition.

Cultivation of Bluetongue Virus in Fertile Eggs produced on a Vitamin-deficient Diet

Two of us (R.A.A. and J.H.M.) have made many unsuccessful attempts to infect mice, guinea pigs, rabbits, hamsters, hedgehogs, and chicks with bluetongue virus. Mice and guinea pigs were not rendered susceptible by blockading the reticulo-endothelial system with India ink, by deep X-ray therapy, or by maintenance on a vitamin-deficient diet of autoclaved oats. Finally no multiplication occurred in normal developing chick embryos when virus was seeded on the chorio-allantoic membrane, or in the yolk-sac (method of Cox, 1938).

Various workers, particularly in the United States, have shown that deficiencies and intoxications can be produced in eggs, if the hens are put on appropriate rations. Thus, eggs may be obtained that are low in vitamins A, D, and E, pantothenic acid, riboflavin and manganese: if the diet contains much selenium, for example, the embryo is poisoned. It occurred to one of us (J.D.W.A.C.) that although bluetongue virus did not multiply in a so-called normal egg, yet it might grow in some of these 'pathological' eggs. We decided to infect eggs produced on a diet known to be deficient in the curled-toe-paralysis preventive factor, which is possibly riboflavin. Eggs laid by hens on a supposedly normal ration were also used, as a control.

In both groups, each hen had free access to water and oyster-shell grit and got about 1·5 oz. crushed yellow maize each evening, and a little more than 0·5 oz. chopped, fresh lucerne each morning. Dry mash was left before the birds all day. The two mashes were made up as follows:

	Deficient Mash lb.	Normal Mash lb.
Yellow maize meal	30	30
Pollard	30	30
Wheaten bran	20	20
Meat and bone meal (55% protein)	7·5	15
White fish meal (68% protein) ..	7·5	0
Lucerne meal (average quality) ..	0	5
Dried brewer's yeast	0	3
Common salt	0·5	0·5

Basing our calculations on American figures, we may assume that a hen given the deficient mash ate about 180 micrograms riboflavin per day. As a hen needs at least 230 micrograms daily for her eggs to develop properly, it is obvious that the deficient ration is low in riboflavin. Hens on the normal mash took in the adequate amount of approximately 270 micrograms riboflavin each day.

We used the above deficient diet because our colleague, J. J. Bronkhorst, had proved in chick experiments that the fish meal and the ration as a whole was very low in the curled-toe-paralysis preventive factor. It was he, too, who kindly supplied all the eggs for these experiments.

The virus for the 'pathological' eggs was a 10 per cent saline emulsion of infected sheep spleen, filtered through an 860 mμ gradocol membrane; 0·2 c.c. was inoculated into the yolk-sac of each egg containing a six-day-old embryo and the eggs incubated at 36° C. Serial passage was carried out every 4 or 5 days by subinoculating yolk-sac emulsion into the yolk-sacs of 'pathological' eggs.

With this technique the virus has been carried through 21 egg-to-egg passages with irrefutable evidence of multiplication. The yolk-sac, the embryo, and the chorio-allantoic membrane contain virus; in one experiment each was shown to hold between 100,000 and 1,000,000 infective doses for sheep.

After 4 passages in 'pathological' eggs, the virus was able to grow in normal eggs and could be maintained in them easily. At the present moment, the adapted virus is in its 37th normal egg passage. One experiment has shown that the virus content of normal eggs may be much lower than that of 'pathological' eggs.

As a rule, infected embryos die in 4 or 5 days, and are cherry-red when dead or dying.

Whether it really is the deficiency of riboflavin in the diet that has enabled us to propagate bluetongue virus in 'pathological' eggs remains to be seen, and experiments will soon be conducted to settle the question. At least twenty deficiencies and intoxications and combinations of these can probably be produced in eggs, and it would seem as if 'pathological' eggs might support the growth of other viruses that have not been cultivated in normal eggs. However, we may mention that neurotropic and viscerotropic strains of horse-sickness virus and the rickettsias of rat typhus and tick-bite fever multiply no better in 'pathological' than in normal eggs.

Pining in Sheep not Curable by Cobalt Administration

Work in Australia has shown that deficiency of alt in the diet is responsible for characteristic orders of sheep and cattle. The view that a sheep ease known as 'pining' results from cobalt de- ncy was advanced by Corner and Smith[1], who med that cobalt administration prevented and d this disease north of the Scottish border. In opinion these experiments were inadequately trolled. During a large-scale investigation of ing' in the Cheviot area south of the border, ertaken in collaboration with Dr. Taylor and . Green of the Veterinary Laboratory of the nistry of Agriculture at Weybridge, a well-con- rolled experiment was carried out to test the curative effect of cobalt on sheep suffering in varying egree from this disease. Cobalt solution was ad- inistered for five months to one half of the sheep, e other half being left as untreated controls. The ath-rate from 'pining' was as high in the treated as untreated group, and at the end of the experiment treated sheep were no better than the controls udged by body-weight records and hæmatocrite mations. The details of this experiment have n described in a recent number of the *Veterinary ord.*

n a preliminary report[2] the view was expressed us that 'pining' in the area concerned was caused interaction between malnutrition and parasitic festation, the worm species *O. circumcincta* being pecially incriminated. Field investigation over the t three years has shown that 'pining' may be evented either: (1) by feeding a special mineralized ke containing considerable quantities of calcium l phosphorus as well as small amounts of iron, balt, copper and other trace elements; or (2) by stematic anthelmintic treatment to remove worms. e mineralized cake may have prevented 'pining' y removing specific mineral deficiencies or by obviating undernutrition in the more general sense y supplying additional protein and calories. Al- ough administration of cobalt has failed to cure ning, the possibility is not ruled out that specific ficiency of this element may play an initial part in me areas in the cause of pining by lowering re- tance to parasitic disease. There is, however, no dence for this view apart from the fact that sitic infestation has been controlled and 'pining' vented by feeding a mineralized cake containing alt as well as other trace elements. Our investi- ions are being extended with the object of eliminat- the non-essential constituents from the pining- venting cake and continuing observations upon thelmintic treatment.

The claims of Corner and Smith for the specific nificance of cobalt have been recorded in bio- emical and medical as well as in agricultural erature, and it is therefore thought of general terest to direct attention to the article entitled Pining not Curable by Cobalt Administration" ing published in the *Veterinary Record*.

Practical Science in Schools

A communication from my former biology master, Mr. A. G. Lowndes, in Nature of June 1, p. 863, cannot, I feel, be allowed to pass without an answer. Since the time when I was very ably taught by Mr. Lowndes with plenty of laboratory work, I have become a biology examiner both in scholarships and School Certificate. I have, therefore, experienced the results of laboratory work in biology at school from two aspects in quite a short space of time, and my conclusions are the very opposite to those expressed by Mr. Lowndes.

Candidates for scholarships come up knowing advanced genetics, but when presented with a twig of larch they do not recognize it nor can they make a constructive effort to understand it. Similarly, they know all the details of stomatal mechanism, but the stoma that they draw would be quite incapable of opening and closing as described, and in one case a candidate admitted that he had never really properly examined one. I can, therefore, only believe that this result is achieved by too much book and lecture work and too little laboratory work. On Mr. Lowndes' scheme there will be a tendency for children to acquire knowledge which they do not properly understand because they have not handled the material for themselves.

Furthermore, I sincerely believe that a plant or animal which has been handled and cut up can be remembered very much more readily than the same plant or animal described and demonstrated. I remember that I learnt very much more of plant systematics at school when I collected and identified two hundred flowers than at the University when I saw many of them as demonstrations.

In this letter I only feel qualified to refer to biology, and so I may perhaps add that I believe one great asset of laboratory work is that one learns to draw accurately what is observed, and there cannot be too much of this, especially as many who come up to the university are very poor in this respect.

As I understand the problem, the solution would be for the universities to demand a smaller syllabus so that adequate time is allowed for laboratory work and the student becomes really grounded in the fundamental facts. I also find it difficult to subscribe to a statement quoted in an article on the same subject in the same number, namely, that the function of the teacher is "to stimulate wonder and imagination". I should have thought that a better function would be to stimulate understanding and appreciation.

I realize that *elementary general biology* is perhaps in a different category but I would still maintain my thesis, namely, that, so far as possible, actual examination of specimens helps one to remember better than any amount of talking.

V. J. Chapman.

Botany School,
Cambridge.
June 2.

We are glad to publish the above views of a member of a university staff who has also examined school students of biology. It should be borne in mind, however, that the majority of secondary school students do not proceed to a university, and furthermore only a minority of those who do so continue their studies in the science faculties. Science in schools, therefore, is only one of several disciplines and should be treated as such. Over and over again the criticism that the school curriculum caters too much for the university candidate and too little for that majority, who complete their 'formal' education at the School Certificate stage, has been made in NATURE and elsewhere. This criticism is now meeting with a certain amount of response. Science teaching is still too much concerned with the presentation of factual information, by experiment or otherwise, and too little with its social and humanistic contacts. It is not the business of the schools to train academic, professional and industrial experts, but rather to produce intelligent and knowledgeable citizens. Dr. Chapman's views are justified from the point of view of a biologist looking for good, sound biological material to train as specialists. That scholarship candidates "come up knowing advanced genetics, but when presented with a twig of larch they do not recognize it" betrays an unbalanced syllabus. School science should "reveal the influence of scientific thought and achievement in the evolution of our present-day civilization—an appeal to social interest and utility". It has been shown that "factual knowledge and knowledge of scientific method can be imparted as successfully by demonstration as by practical work". While not advocating the complete abolition of practical work, we consider that *in schools* there is too much of it; it is too elaborate and demands more time than can be justified. (Editors of NATURE.)

Relation of Working Period to Output

THE production drive in Great Britain which started a month ago has led to a very great extension of working hours throughout industry. We would urge that this matter should receive the att
scientists for the following reasons. It is
that a scientific attitude should be mainta
wards the relation between hours of work
ductivity of factory labour ; it was establ
experience during the War of 1914–18 that i
hours of work did not in all circumstances
greater production. Scientific workers as
factory hands in industry and in Governmen
are also being asked to work longer hours,
uncertain what holidays will be granted.

During the "emergency fortnight" which
the middle of May, several large firms requi
staff to work a seven-day week of total hours
from 50 to 70. We understand that in some
firms the emergency arrangements have now
an end : but even in these cases the 'pe
arrangements provide for a six-day week
hours, and the question of holidays has
fixed.

While it is difficult to assess the producti
scientific laboratory, it is evident that excessi
and reduced holidays and rest periods are
reduce the rate at which scientific and
workers conduct their theoretical, experim
supervisory work, and will also affect the q
the work. It is also important to remem
mistakes made in scientific work may ha
serious consequences, not only in increasing
of injury to the workers but also in turning o
products.

Points from Foregoing Letters

In a note on the early use of current-bedding to determine orientation of strata in the Dingle Peninsula, Eire, A. Lamont raises the question of the parts played by Patrick Ganly, John Kelly, and possibly G. V. Du Noyer in the application of this technique.

The cross-section of atomic oxygen for elastic collision with electrons has been computed using quantum mechanics by S. K. Mitra, B. B. Ray and S. P. Ghosh. Atomic oxygen is found to exhibit the Ramsauer effect, and the value of the collisional frequency in Region *F* (where atomic oxygen is predominant) computed by taking the appropriate cross-section, agrees with that obtained from radio measurements. Calculation by taking the gas-kinetic cross-section yields too low a value for the collisional frequency.

On examination of the diagrams that have been said by Messrs. Riley and Fankuchen to show the Patterson projection to be expected from an insulin crystal on the cyclol hypothesis, D. M. Wrinch finds that the angle of tilt used in their construction was not 6°, as stated by them, but 36°, and that the evidence of the diagrams is in favour of the cyclol hypothesis.

Investigating the hydration of anilides of higher normal fatty acids, B. A. Toms reports that ability to 'bind' water is shown only by those in which the fatty chain contains more than 14 carbon a
is suggested that the bound water is he
micellar structure.

factor, lowering the resistance of sheep
infestation, death ultimately occurring from
disease.

RESEARCH ITEMS

-Groups and Castes

E distribution of blood-groups in certain castes e United Provinces of India has been studied N. Majundar of the University of Lucknow *ce and Culture*, 5; 1940). Recently tests were d out in connexion with an anthropometric y. Tests on 175 subjects belonging to three gave results as follows: Kayasthas (47) ·4, A 19·7, B 30·6, AB 8·3; Khatris (36) 6·5, A 21·8, B 35·0, AB 6·7; Chamars (92), 38·3, A 13·3, B 38·3, AB 10·0. Bengal data MacFarlane) show that percentages of A and B rease from the higher to the lower castes, and that highest percentage of O is among the caste dus. The increase of B among the Khatris of the ted Provinces is perhaps due to a greater ad- ure with inferior races. The Chamars possess a percentage of B and O—38·3 O as against O among non-caste Hindus of Bengal; while Kayasthas have 41·4 O. On these results it is ature to form any hypotheses; more data are ired. The castes have been endogamous groups ges. If O underrates the degree of isolation, the large percentage of O in India (43·0) among hmins and Kayasthas of Bengal and (41·4) ng Kayasthas of the United Provinces, compared 5·0 among Americans, 46·4 among English, 37·3 Germany, indicate a racial affiliation with the ious branches of the white race. On the other d, if there may be genes for O in the low-caste e with a high mutation rate for B, the decrease ng the higher castes of A, which is higher among white races, and a high value of B suggest a ial admixture, and the more we know of blood- oups the greater the possibility of determining the xtent of this admixture. The popular belief that he Kayasthas of Bengal differ ethnically from those the United Provinces is not supported.

of a Blind Cave Fish

HE blind cave characin, *Anoptichthys jordani*, ribed in 1936 is the first fish of the order Hetero- ni to show loss of ocular structure. A histological tigation of the eye by E. B. Gresser and C. M. ler, jun., shows that while the eye has definite rs, they are of poor development, so that while primitive optic vesicle has undergone its first agination, it appears at this stage to have ceased differentiate beyond a pigment layer and a retinal er (*Zoologica*, 25, 113; March 1940). The external sculature is present and an optic nerve has an line. Whether the eye stops in development ause no lens develops and produces in turn the on of the poorly developed primary vesicle into yst, or vice versa, the eye has not advanced to a ge when vision is possible. The authors consider t the histology indicates that in this case blind- s is due to a stoppage in development of the eye ctures at an early stage, rather than to de- erative changes at a more advanced stage; and y consider that the origin of such a defect as is recorded is more likely to be due to a chance ant form accidentally associated with cave life, to the gradual adaptation of a seeing fish to conditions of cave darkness.

A New Method of Rendering a Poisonous Snake Harmless

Recently, Duval B. Jaros has perfected an electro-coagulating device, with high-frequency current at about one million cycles a second, whereby the escape of venom from the poison gland of a snake and its passage to the fang is prevented by the destruction of a portion of the duct (*Zoologica*, 25, 49; March 1940). The operator can manage the entire procedure without assistance and in safety; the snake is not disfigured and its habits seem in no wise affected by the operation. Thirty-six crotalid snakes, ranging in size from eight inches to four feet, were treated and were thriving normally after forty-five weeks, the result of the occlusion of the duct apparently being permanent. In the performance of the operation the author introduced three novelties, a practical device for holding the snake, a cheap and efficient operating knife, and the use of Michel surgical clips to eliminate all danger of the operator being bitten.

Mycology in China

Several papers which show increasing study of mycology in China were contributed to the journal *Sinensia* in 1937 and 1938. S. C. Teng and S. H. Ou published part 7 (9, Nos. 5–6; September 1937) and S. C. Teng part 8 (9, Nos. 3–4; May 1938) of "Additional Fungi from China". S. C. Teng and K. L. Teng have also made a preliminary study of the Myxomycetes of China (8, Nos. 5–6; Sept. 1937). These are all detailed descriptions of species, most of which are familiar to the British mycologist, but a few new taxonomic designations have been found necessary. These include *Quaternaria microspora*, *Rosellinia culmicola*, *Clypeosphœria radicicola*, *Endoxylina citricola*, *Chrysomyxa Bambusae* and *Periconia bambusina*. The two last-mentioned occur on bamboo; the others upon deciduous twigs. Some of the work of description was performed in Nanking in October and November 1937, during the disastrous air-raids upon that city.

Life-cycle of Allomyces

Ralph Emerson has described a genetical means of discovering the life-cycle of Allomyces (*Mycol. Soc. Amer.*, Dec. 30, 1939). Species of the sub-genus Euallomyces have an asexual generation alternating with a sexual one. Zygospores give rise to secondary sporophytes, while spores from resistant sporangia give rise to sexual plants which are monœcious. The sexual plants bear male and female gametangia of different colour, and their position differs in different species. Crosses were made between species differing in these and other characters. Segregation occurs after the formation of resistant sporangia, but before the development of the mature gametophyte. The sex-determining mechanism is, therefore, phenotypic in the gametophyte.

Linkage Group in the Sweet Pea

The fourth linkage group of the sweet pea now consists of five pairs of genes (R. C. Punnett, *J. Genetics*, 39, 301–308; 1940). The characters acacia, dull flower, absence of flake-modifier, glabrous, picotee, together form a linkage group of at least 119 cross-over units. C. D. Darlington in an appendix to this paper shows that the largest two chromosomes are about 148 crossing-over units long; therefore this linkage group covers almost the whole of one of these long chromosomes. A further allelomorph G'' has been added to the flake multiple allelomorph series G, G'. G'' causes less pigment production than G'.

Genetics of Wood-Lice

THE woodlouse, *Armadillium vulgare*, is a fairly easy animal to rear in culture (H. W. Howard, *J. Genetics*, **40**, 83–107; 1940). Two varieties, red and yellow, respectively, are dominant to the commoner black and grey varieties, while two rare varieties *C* and *D* are dominant and sex-linked. The sex ratios of a progeny is rarely 1 : 1; some broods consist only of males or only of females, while others are weakly arrhenogenic or weakly thelygenic. This is determined by the female parent. The author follows Vandel's hypothesis that the female is the heterozygous sex, and that the segregation of the sex chromosomes into eggs and polar bodies is controlled by the cytoplasm. Several wild populations of *A. vulgare* were found to have an excess of females.

Applications of Statistics to Palæontology

As a result of a statistical investigation of some freshwater lamellibranchs (Anthracomya) from the Coal Measures of Scotland (*Quart. J. Geol. Soc.*, **96**, 13–37; 1940), D. Leitch has developed a method which may prove of wide application in the study of fossil groups where abundant specimens are available showing wide ranges of variation in which they appear to overlap with comparable groups at other stratigraphical horizons. He finds that regression equations calculated on various dimensions of these shells are applicable to practically all the members of the group investigated, but that a large proportion of the forms from other horizons do not satisfy the equations.

Mechanical Integrity in a Circuit-Breaker

A PAPER on the "Mechanical Integrity in the Design of Electrical Circuit-Breakers" was read before the Institution of Electrical Engineers on May 8 by M. C. Hunter, of the British Thomson-Houston Co., Ltd. Electrical investigation has been carried out since the inception of the electrical circuit-breaker to produce infallibility of operation, and more particularly to ensure that the breaker will open when required to do so, regardless of the time it may have remained in a state of rest, under load conditions, without attention. There are many other mechanical requirements to be met such as speed of making, speed of breaking, contact pressure and correct buffering for absorption of energy at each end of the stroke, but the quality of 'opening whenever called upon' is the most fundamental of all. No accelerated proving method is available which will fully replace the natural sequence of closing the breaker, leaving it on load for, say, six months and observing the result after tripping. The arrangement of parts, accelerating springs, etc., therefore demands that there shall exist an expelling force which will at all times guarantee the opening of the contacts. The determination of the required magnitude of this expelling force is not easy, and ultimately depends on the required degree of certainty with which the breaker must open under the most onerous conditions, such as inattention, rust, 'glueing in' with heat, slight freezing of the contacts, misalignment, contact roughness due to wear, contact erosion, etc. T required value may be considered to be in the natu of a 'factor of safety', or better a 'factor of assuran This term is used in connexion with both the brea mechanism and the operating mechanism. author, by means of curves and calculations, sh how approximate values of this assurance factor be obtained which would be of value in practice.

Precision Measurements in the Hydrogen Spectrum

AMONG the fundamental applications of quan theory to atomic spectra are the quantitative calc tion of the Rydberg constant in terms of *e*, *h*, *c*, and the prediction of the fine structure of the Ba lines. The latter, as calculated from the relativ wave-mechanics of Dirac, is the same in separa and intensity distribution as that given by the theory of Sommerfeld. J. W. Drinkwater, Sir O Richardson and W. E. Williams (*Proc. Roy. S* A, **174**, 164) have investigated the wave-lengths structures of the α-lines of hydrogen and deuter using the reflecting echelon of Williams, which this purpose a new and advantageous spectros technique. The source of light was a discharge cooled in liquid air. The value of *e/m* for the el calculated from the wave-lengths is in good a ment with recent measurements on free elect This removes a suspicion that there was a systen difference between 'spectroscopic' and 'free elec values of this ratio. The separation and inten of the fine structure components were in satisfa agreement with the theory. The limit to the acc of this test was apparently set by a backgroun the hydrogen molecular spectrum.

Energy in the Solar Ultra-Violet

A REPORT of five years work at the Mount Wil Observatory on the energy distribution in the ul violet solar spectrum has recently been published E. Pettit (*Astrophys. J.*, **91**, 159; 1940). Th observations differ from the author's previous wor at Tucson, Arizona, in being on the radiation from the centre of the disk, rather than on integrated sunlight. The light was fed from an aluminized sidereosta mirror through a double quartz monochromato o to a vacuum thermopile, the second slit of the monochromator being made adjustable so as to pass 100 A. of the spectrum at all wave-lengths. The results, reduced to no atmosphere by transmission coefficients which agree well with those of the Smithsonian observers, yield spectral energy curves similar to those obtained at Tucson: the intensity drops by 50 per cent between 4000 A. and 3800 A., remains nearly constant to 3250 A., and then falls at a linear rate with wave-length to a very low value at 2920 A. To eliminate so far as possible the effect of Fraunhofer line absorption, auxiliary energy-curves were ob tained with a 21-ft. concave grating monochromat used in conjunction with a photocell. By sketchin in the continuum between the lines on such trac coefficients were derived by which the thermoelect curve could be reduced to one referring to the c tinuum. Even so, however, this curve shows most the previously noted depressions in the ultra-viol and is still far removed from that of a black bod The absorption spectrum of O_3, which has form the subject of a special laboratory investigation, shown to be insufficient to account entirely for form of the curve, and its departures from the bla body type are to be regarded as real.

RECENT ADVANCES IN MARINE BIOLOGY

BY DR. N. B. EALES

HE recently published Journal of the Marine Biological Association contains nineteen papers biological subjects, and the report of the Council the year 1938.* The report records the bequest the Association of £6,500, instruments, books and paratus under the will of the late E. T. Browne. research room has been named the Browne morial Room, and will contain furniture from . Browne's laboratory and his valuable reference rary on Cœlenterata. The new constant tempera- e rooms are in use and other improvements have en made in the buildings, especially in accommoda- n for research workers.

Six papers record ecological investigations. P. rtley gives an account of the tuck-net fishery on fine mud of the Tamar and Lynher estuaries. net was used at monthly intervals for two years e Saltash area, and the estuarine fishes, their , migration and frequency distribution are ribed. Most of the fish go to the sea to spawn. iteral invasions of cormorants, jellyfish and nalopods seriously impair the value of the ng.

. Milne, in the fourth of his studies on the ecology ie Tamar estuary, deals with the fauna and flora oating buoys. Weeds attach themselves in con- rable numbers and compete with mussels for a Sessile animals are to be expected, but isopods, hipods, crabs, worms and echinoderms live in the ices. As the result of permanent submergence, wever, some littoral species cannot survive, for ample, *Littorina littorea*. The extent of estuarine netration was studied.

J. Colman surveyed the well-known collecting area nown as Church Reef, Wembury Bay, and examined he invertebrate fauna in relation to eight species of seaweed. He records 35 animal species new to the Plymouth Fauna List, out of a total of 177. There re surprising omissions, for example, *Obelia geniculata*, Tectibranchs and Nudibranchs, and the compound Tunicates *Didemnum asperum* and *D. maculosum* on the Laminaria holdfasts. A large number of Polychætes was found. A comparison of terrestrial and marine faunas elicits the fact that the marine fauna is the denser of the two. *Ascophyllum nodosum*, with its epiphyte *Polysiphonia lanosa*, houses the greatest number of individuals.

C. Rees studied the ecology of a mud flat in the Cardiff area, by means of horizontal and vertical samples. The microfauna and the chemical and physical factors of the water were investigated and quantitative survey of the macro- and micro-fauna ere attempted. The interactions of the observed henomena are discussed.

H. B. Moore, in his second paper on the biology *Littorina littorea*, made a survey of the zonation this species in five localities in the Plymouth area d one on the island of Skye. Unable to endure nstant immersion, this species has a definite lower it; it does not extend below low-water springs l is most abundant at mean low water of the neap es. The upper limit varies with the locality and algal growth, but the molluscs require wetting by the sea every tide, and do not reach above high water neaps. Young individuals occur near the upper limit, the largest near the lowest levels. G. Spooner and H. B. Moore, in their sixth paper on the intertidal muds of the Tamar estuary, record the macrofauna. Quantitative samples were taken and provided data regarding population density, up-river penetration and vertical distribution. The effects of water currents at low tide levels on population and the zonation of certain species were also studied. This fauna supplies food for fishes brought in by the flood tide and for wading and shore birds during the ebb tide period. The paper is profusely illustrated with graphs and distribution charts.

There are three papers dealing with life-histories. E. H. Myers worked on the life-cycle of four species of the foraminiferan Discorbis. Since the flagellate stage occurs within the test, it is possible to demonstrate the production of 'zoospores' by crushing. In *D. patelliformis* 250–300 triflagellate zoospores—more correctly gametes—are formed within one shell. At this period, however, two or more individuals unite to form multiple tests, each participant being a mononucleate megalosphere. After fertilization of the gametes multinucleate microspheric individuals with two or three chambers are formed within the megalospheric test, and each undergoes asexual reproduction to form mononucleate megalospheric individuals again. The complete life-cycle can be completed in just over 64 days.

Marie Lebour adds to her valuable researches on the larval stages of Crustacea an account of the larvæ of the Pandalidæ. F. Gross has two papers dealing with the life-history and osmotic relations of the diatom *Ditylum brightwelli*.

Contributions of a biochemical and physiological nature include a study of the nitrogenous and phosphorus requirements of phytoplankton, and the intensification of their growth rate by chemical means by H. Harvey, of the phosphorus and iron requirements of two species of Sagitta by R. J. Harrison, and on the average obliquity of illumination under water by W. Atkins and H. Poole. They describe a cubical photometer for obtaining their results.

The variation in the type of inheritance shown by echinoid hybrids in different years led S. Hörstadius to study crosses between *Psammechinus miliaris* ♀ (*Z* type from the shore and *S* type from the Eddystone) and *Echinus esculentus* ♂. It is remarkable that during 1909–11 the inheritance was maternal, in 1912 it was paternal, while in 1932 it was mixed. The effects of temperature, *p*H and salinity are discussed, but no definite cause for the difference was established.

There are three investigations on subjects of economic importance. F. S. Russell continues his records of the seasonal abundance of young fish, although unfortunately, owing to the War, the record for 1939 stops at the end of August. Previous records show that the last four months of the year are negligible, since the earlier months cover fully the period of production. The 1939 results are the worst

---

Journal of the Marine Biological Association of the United Kingdom, 24, No. 1. (Cambridge: At the University Press, 1940.)

since the slump year of 1924, despite the fact that no change in the plankton was noted. J. H. Orton reports on the oyster beds of the Fal Estuary. On the banks the beds are in poor condition, largely owing to dirty culch. Overgrowth of sponges and Lithothamnion is a troublesome factor. In the river, conditions are better and it is suggested that clean culch from this region should be spread over the banks every June to assist in recovery. *Crepidula fornicata* has not appeared in the area. The experimental rearing of oyster larvæ over five seasons at Port Erin Biological Station provides the material for a lengthy report by J. M. Bruce, Margery Knight and Mary Parke. This important piece of work deals chiefly with the food supply of the larvæ, an cultivation of algal zooids acceptable to them. in some respects supplementary to H. A. work on the biological and physical condi affecting oyster culture at Conway. Six flag organisms were eventually chosen and cultivate were fed to the veliger larvæ under stabilized physical conditions, either separately or mixed. most successful were those labelled H and I, gre yellow or golden brown flagellates 3–6 μ in diam Using them as food, more than 90 per cent o larvæ settled as spat. The adaptation of the ex mental results to commercial practice is the problem to be solved.

LARGE-SCREEN TELEVISION PROJECTION

THE application of television has so far been restricted by the difficulty of obtaining received pictures comparable in size and brightness with those produced by the cinematograph, whether used in the home or in places of public entertainment. Consideration of the matter leads to the conclusion that this objective is unlikely to be achieved until it is practicable to apply the principles of optical projection of the pictures, using a standard form of light source of a magnitude suitable for the size of picture required.

In an article published in the February–March issue of *Electronics and Television and Short-Wave World*, Dr. A. H. Rosenthal describes a new electronic device by means of which such projection may be realized, without the disadvantages accompanying the use of an intermediate film on which the picture is first recorded photographically and then projected in the usual manner. The principle of the device is based upon the discovery by E. Goldstein in 1894, that certain materials, normally transparent to visible light, become coloured, that is, more or less opaque, when they are subjected to bombardment by cathode rays. Examples of such materials are the halides of the alkaline earth group, and potassium chloride has been used in the application of this discovery to television reception.

In the instrument developed by Dr. Rosenthal, which he terms a 'Skiatron', the screen of the cathode-ray receiving tube is replaced by a plate of potassium chloride crystals, mounted between two light-transparent electrodes. As the plate is scanned in the normal manner by the beam of electrons, opaque deposit is produced, the density of whic everywhere proportional to the instantaneous tensity of the beam. The screen thus carries du each frame period a complete quasi-statio picture, which may be projected optically in a ma similar to that employed with a cinematograph The opaque deposit is removed by the applicatio a steady electric field between the electrodes pl on either side of the crystal, the speed of oblitera increasing with the field strength and also increase of temperature of the crystal.

In the instrument under development, the nitudes of these quantities are chosen so that 'picture' deposits are removed in the interval betw successive scannings. Owing to the fact that picture being projected is quasi-stationary, as c pared with the continuously varying one produ on the fluorescent screen of the usual cathode- tube, the picture repetition frequency used in 'Skiatron' can be reduced to a value just sufficient avoid flicker. If this advantage is substantiated practice, the effective band of radio frequencies quired by the television transmitter will be reduc

In the article referred to, Dr. Rosenthal illustra an arrangement of using three of these special tu for reproduction of coloured pictures. Each catho ray tube with its special crystal screen and a suita light filter operates at one of each of the th primary colours used, and the illumination is p jected directly through the three screens in successi to obtain the coloured resultant picture.

PROBLEMS OF EVACUATION

THE report of an inquiry, which has been pursued by the Department of Social Science of the University of Liverpool, financed by a grant from the Charities Fund of the Liverpool Council of Social Service, into problems of evacuation has now been published under the title "Our Wartime Guests—Opportunity or Menace" (Liverpool: University of Liverpool Press. London: Hodder and Stoughton, Ltd., 6*d*. net). It emphasizes the importance of a determined effort to profit as much as possible from the mistakes of what may prove to be only the first of a series of evacuation schemes. Like the interim report, which dealt with the evacuated areas, the present report is based on house-to-house visiting, this time in the recepti areas. The results of these 412 interviews lead to reassuring conclusion that the evacuation schem despite its voluntary basis, has not entirely brok down. The majority of the hosts behaved splendi and succeeded in making the children entrusted them happy. Many of the parents co-operated to best of their abilities.

That the scheme was not a complete success w due to faulty organization in the billeting of dirt verminous and enuretic children; the removal children from their billets by parents on the impul of the moment; the unwillingness of some hosts
